

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

INDEX TO VOLUME CXXX.

- Abbott, A. C.** Chemical, physical and bacteriological studies of air over decomposing surfaces, with especial reference to their application to the air of sewers, 568.
- Abbott, S. W.** National registration a necessity, 137; recent progress in public hygiene and preventive medicine, 337.
- Abdominal Surgery.** Cases of abdominal surgery occurring in the practice of Dr. J. Collins Warren at the Massachusetts General Hospital during the winter of 1893, Scudder, C. L., 1, 29.
- Absinthe.** The poisonous properties of absinthe and its congeners, 462.
- Achorn, J. W.** The effect of climate and environment on the New England girl, 58.
- Acting Assistant-Surgeons,** 226.
- Alcohol.** The rôle of alcohol in the causation of cirrhosis of the liver, 324.
- Allen, G. W.** Two cases of litholapaxy, 383, 388.
- Allen, H.** Morphology as a factor in the study of disease, 567.
- American Gout,** 273.
- American Medical Association.** Revision in the, 635; San Francisco meetings, 635, 637.
- Anæsthesia.** Mr. Lawson Tait's use of anæsthesia, 250.
- Anarchist.** Autopsy on the Greenwich anarchist, 326.
- Anatomy.** Recent progress in anatomy, Dwight, T., 7, 468; morphology as a factor in the study of disease, Allen, H., 567; Association of American Anatomists, 622; the range and the significance of variations in the human skeleton, Dwight, T., 625.
- Aneurism.** A new and distinguishing sign of latent aneurism of the aorta, Glasgow, W. C., 651.
- Animal Experimentation,** its influence on medical science, Loomis, A. L., 545; resolution before Congress of American Physicians and Surgeons, 630.
- Appendicitis,** with apparent resolution of abscess, relapse, death, autopsy, Peckham, F. E., 61; specimen of gangrenous and perforated appendix, Richardson, M. H., 67; infectious appendicitis, Morris, K. T., 133; recurrent appendicitis, August, A., 186; an appendix obliterated in the greater part of its length, Richardson, M. H., 192; cases of appendicitis presenting unusual features, Richardson, M. H., 232; twelve consecutive and successful operations for appendicitis, Keefe, J. W., 282, 306; a case of appendicitis, Folsom, C. F., 342; the after-treatment of operations for appendicitis, Burrell, H. L., 433, 444; specimen of appendix, Elliot, J. W., 444; some impressions derived from an experience of forty-four cases, Gage, H., 608.
- Arm.** Amputation of the entire upper extremity (including the scapula and clavicle) and of the arm at the shoulder-joint, Keen, W. W., 565.
- Army.** The duties of army medical officers, 49; the Army Medical School at Washington, 100; proposed reduction of the Army Medical Department, 294; proposed reduction of the Army Medical Corps, 351; the proposed reduction in the Army Medical Service, Parker, W. T., Dawbarn, R. H. M., 430; scaling the appropriation for the Library of the Surgeon-General's Office, 475; infantry footwear, 478; reduction of medical officers in the army, 590.
- Arsenic.** Chronic arsenical poisoning from wall-papers and fabrics, 246.
- Asepsis.** Obstetrical asepsis, Price, J., 32, 40.
- Ashhurst, J., Jr.** The surgical treatment of empyema, 564.
- Asthma.** Hypnotic suggestion in the cure of asthma, 350.
- Athletic Sports,** Elliot, C. W., 197.
- August, A.** Recurrent appendicitis, 186.
- Babcock, R. H.** A report of cases of chronic heart disease treated by the Schott method of baths and gymnastics, 651.
- Bacteriology.** The microbe of scarlatina, 73; bacteriological cultures from a case of puerperal septicæmia, Morse, J. L., 140, 142; a bacteriological study of four hundred cases of inflammation of the throat occurring in diphtheria and scarlet fever, with special reference to pathogenesis, Morse, J. L., 162, 182; the bacteria of peritonitis, 271; the bacteriology of nephritis, Sternberg, G. M., 573; sunshine and microbes, 603; Dr. S. C. Martin's researches on the bacteria of vaccine, Ernst, H. C., 622; modification, temporary and permanent, of the physiological character of bacteria in mixed cultures, Smith, T., 647; the effect of various metals on the growth of pathogenic bacteria, Bolton, M., 647.
- Bagdad.** A sanitary sermon in diagram, Sundberg, J. C., 77.
- Bates, E. A.** A case of tuberculous pericarditis with enormous effusion; general tuberculosis; autopsy, 7.
- Beck, C.** Laminectomy for tubercular disease of the spine, 220.
- Bell, E. E.** A case of myxœdema, 364.
- Beri-Beri,** Daland, J., 652.
- Bibliography.** Adams, W., on contraction of the fingers and on "hammer toe," 122; Ashhurst, J., Jr., the principles and practice of surgery, 395; Baldy, J. M., an American text-book of gynecology, medical and surgical, 653; Bartholow, R., a practical treatise on materia medica and therapeutics, 194; Beard, G. M., a practical treatise on nervous exhaustion (neurasthenia), its symptoms, nature, sequence, treatment, 221; Berry, G. A., disease of the eye, 396; Boston Board of Health, twenty-second annual report, 662; Bozall, R., the use of antiseptics in midwifery, their value and practical application, 317; Brauwell, B., atlas of clinical medicine, 246; Brodie, C. G., dissections illustrated, a graphic hand-book for students of human anatomy, 345; Buck, A. H., supplement to the reference hand-book of the medical sciences, 293; Buxton, D. W., anæsthetics, their uses and administration, 221; Carnichael, J., disease in children, 169; Cathcart, C. W., descriptive catalogue of the anatomical and pathological specimens in the museum of the Royal College of Surgeons of Edinburgh, 71; Coplin, W. M. L., and Bevan, D., a manual of practical hygiene, 169; Corning, J. L., treatise on headache and neuralgia, including spinal irritation and a disquisition on normal and morbid sleep, 631; Crooker, H. E., diseases of the skin, 45; Donkin, H. B., diseases of childhood, 283; Dunglison, R., a dictionary of medical science, 71; Eccles, A. S., sociætica, a record of clinical observations on the causes, nature and treatment of sixty-eight cases, 71; Firebaugh, E. M., the physician's wife, and the things that pertain to her life, 369; Galton, D., healthy hospitals, observations on some points connected with hospital construction, 369; Gray, H., anatomy, descriptive and surgical, 19; Hart, E., hypnotism, mesmerism and the new witchcraft, 19; Hewitt, F. W., anæsthetics and their administration, 546; Hilton, John, rest and pain, 317; Holden's manual of the dissection of the human body, 369; hospitals, dispensaries and nursing, 394; Hyde, J. N., practical treatise on diseases of the skin, 631; Jackson, G. T., a practical treatise on diseases of the hair and scalp, 522; Jacobson, W. H. A., the diseases of the male organs of generation, 19; Jenner, W., lectures and essays on fevers and diphtheria, 1849 to 1879, 122; Johns Hopkins Hospital reports, report in gynecology, 11, 546; Jules, H. E., a hand-book of ophthalmic sciences and practice, 622; Keen, W. W., operation blanks, 346; Kirchhoff, T., hand-book of insanity, 293; Landis, H. G., how to use the forceps, 346; Macready, J. F. C. H., treatise on ruptures, 575; Madden, T. M., clinical gynecology, 11; Massachusetts State Board of Lunacy and Charity, report for 1893, 72; Manley, T. H., hernia, its palliative and radical treatment in adults, children and infants, 473; Marinesantitätsordnung, 473; Martin, E., essentials of minor surgery, bandaging and venereal diseases, 122; Mathews, J. M., a treatise on diseases of the rectum, anus and sigmoid flexures, 321; Musser, J. H., a practical treatise on medical diagnosis, 396; Norris, R. C., syllabus of the obstetrical lectures in the medical department of the University of Pennsylvania, 420; Parkes, L. C., infectious diseases, notification and prevention, 396; Pepper, W., a text-book of the theory and practice of medicine, 369; physician's visiting list for 1894, 71; Pye-Smith, P. H., an introduction to the study of diseases of the skin, 20; Schenk, S. L., manual of bacteriology, 44; Seun, A., a syllabus of lectures on the practice of surgery, 71; Surgeon-General's Office, U. S. A., index catalogue, vol. xiv, 223; Stearns, H. P., lectures on mental diseases, 317; Stillé, A., and Malsch, J. M., the national dispensatory, 345; Tebb, W., the recrudescence of leprosy and its causation, 20; Thompson, H., introduction to the catalogue of the collection of calculi of the bladder, 191; Tuke, D. H., reform in the treatment of the insane; early history of the Retreat, York; its object and influence, with a report of the celebration of its centenary, 19; Von Kraft-Ebing, R., pycopathia-sexualis, with especial reference to contrary sexual instinct, a medico-legal study, 19; Webster, D., eye-strain a cause of headache, 631; Wharton, H. R., minor surgery and bandaging, 653; Whittaker, J. V., the theory and practice of medicine, 283; Wimmer, S. J., Wimmer's table and notes on human osteology, 420; Witthaus, R. A., the medical student's manual of chemistry, 20; a laboratory guide in urinalysis and toxicology, 473; Witthaus, R. A., and Becker, T. C., medical jurisprudence, forensic medicine and toxicology, 395; year-book of treatment for 1894, 473; Zola, Lourdes, 654.
- Bicycle.** The pathology of bicycling, 197.
- Billings, J. S.** Methods of teaching surgery, 635.
- Biography.** Arnold, J., 480; Billings, L. F., 52; Billroth, T., 176; Briggs, C. E., 660; Brown-Séquard, 352, 370; Chrenow, 23; Codman, B. S., 2, 8; Conway, W. A., 424; Cray, D., 432; Cresson, C. M., 2;

- Cunningham, W. F., 636; Dagna, G., 300; Day, A., 456; Donovan, 200, 228, 251; Elder, E. S., 636; Fogg, W. J. G., 251, 252; Ford, C. C., 404; Forsaith, F. F., 276; Garcia, V. A., 276; Grierson, G. T., 128; Guttman, S., 28; Hartnett, M. K., 528; Hassall, A. H., 456; Hill, H. E., 52; Hilsen, A. H., 300; Hirsch, A., 200; Holmes, H., 149; Hutchinson, William F., 198; Jacob, Ernest H., 328; James, Charles, 549; Keating, W. V., 432; Kundt, A., 636; Lheritier, S. D., 404; Lucke, A., 276; Marston, D. E., 404; Metcalf, T., 455, 456; Michel, M., 636; Nava, J. G., 104; Ollivier, A., 328; Parrish, J., 252; Patterson, J. H., 456; Pike, C. C., 128, 527; Radziminaki, 23; Rauch, J. H., 328; Romanes, G. J., 552; Rubio, F. A., 200; Scheut-hauer, G., 228; Seaverns, J., 252, 327; Smith, C. G., 80; Stanard, A. C., 502; Sperr, 636; Van Beneden, P. J., 52; Walker, J. E., 636; Weld, F. M., 52; Willard, O. A., 52; Workman, J. H., 404.

- Empyema.** The surgical treatment of empyema, Ashhurst, J., Jr., 564.
- Endocarditis.** A case of malignant endocarditis, Fay, W. E., 189.
- Ernst, H. C.** Dr. S. C. Martin's researches on the bacteria of vaccination, 622.
- Ethmoidal Sinuses.** diseased conditions of, Bosworth, F. H., 590.
- Everett, O. H.** A case of pulmonary stenosis in an adult, 207.
- Ewing, C.** The action of rattlesnake venom upon the bactericidal power of the blood-serum, 477.
- Ewing, J.** Address before American Surgical Association, 564.
- Exercise** in the treatment of lateral curvature, Brackett, E. G., 329, 343.
- Extra-uterine pregnancy,** right-sided, followed at an interval of two years by left-sided Fallopian pregnancy, with repeated operation, Harrington, F. B., 6; six cases of extra-uterine pregnancy, Johnson, F. W., 256, 265; cases of extra-uterine pregnancy, Elliot, J. W., 260; ectopic gestation, 270.
- Eye.** Removal of foreign body from the anterior chamber of the eye, 142; two cases of chancre of the eyelid, with an account of the manner of infection, Standish, M., 237, 244; thrombosis of the central artery of the retina with unusual features, Jack, E. E., 312.
- Farlow, J. W.** Hypertrophy in the post-nasal space, especially after childhood, 66, 67.
- Fay, W. E.** A case of malignant endocarditis, 189.
- Feeble-minded children,** 222.
- Fenger, C.** Surgery of the ureters, 596.
- Fischer, W.** The new rational way to sleep, 126.
- Fisher, E. D.** Anomalous cases of general paresis, 15.
- Flek, S. A.** A treatment of typhoid fever, 620; some meteorological data of Colorado, 632.
- Fitchburg.** The sewerage system in Fitchburg, 425.
- Fitz, E. H.** The rise and fall of the licensed physician in Massachusetts, 1781-1860, 528; the legislative control of medical practice, 581, 609, 637.
- Flat-Foot,** Bradford, E. H., 377.
- Folsom, C. F.** A case of appendicitis, 342; cases of traumatic headache, 621, 641.
- Foot.** A case of club-hand and club-foot, Sayre, R. H., 42; the treatment of club-foot by Wolff's method, Shands, A. B., 43.
- Foot-ball vs. Insurance,** Wells, G. W., 76; deafness due to a foot-ball injury, Corning, J. L., 120.
- Forbes, W. S.** The removal of stone in the bladder, with the presentation of a new lithotrite, 600.
- Fox, C.** The treatment of chronic ringworm of the scalp, 373.
- Fractures.** Compound fractures, Mumford, J. G., 463, 471; mooted points as to fractures of the arm, with notice of an improved splint, Gaston, J. McF., 599.
- Francis, G. E.** Three uterine pregnancies during an extra-uterine pregnancy, 199.
- Frank.** Tapping of the lateral ventricles, 401.
- Friedemann.** Blood-pressure in diphtheria, 26.
- Gage, H.** Appendicitis; some impressions derived from an experience of forty-four cases, 508.
- Gall-bladder.** The unfavorable sequelæ of certain radical operations on the gall-bladder, 347.
- Gaston, J. McF.** Mooted points as to fractures of the arm, with notice of an improved splint, 599.
- Gavin, M. F.** The radical cure of hydrocele, 210, 213.
- Gay, G. W.** Malignant disease of the rectum, 204, 214; ligation of both common carotid arteries, 244; letter from Rome, 428; the Medical Registration Bill, 651.
- Generative System.** A case of uterine tumor, Cushing, E. W., 37, 42; the immediate causation of the diseases peculiar to women, Thomas, T. G., 68; review of a summer's work in gynecology at the Boston City Hospital, Blake, J. G., 89, 97; ovariectomy for nervous disease, Edes, R. T., 105; a rare form of the hymen, Draper, F. W., 142; three cases of salpingitis of unusual extent, Richardson, M. H., 159, 169; the radical cure of hydrocele, Gavin, M. F., 40, 213; three years' experience with electrical treatment of fibroid tumors of the uterus, with a report of forty-four cases, Burrage, W. L., 289; the operative treatment of uterine fibroids, Cushing, E. W., 301, 315; imperforate hymen with hæmatocolpos, Green, C. M., 358, 367; mucous cysts of the vagina, Green, C. M., 358; recto-vulvar fistula, Green, C. M., 358; report of progress in gynecology, Davenport, F. H., 364; observations in cases of fibroid tumor of the womb, Minot, F., 405, 419; the non-surgical treatment of chronic pelvic inflammations and their sequelæ, Davenport, F. H., 407, 420; the open incision in uncomplicated cases of hydrocele, Clendenin, P., 440; stricture of the urethra, with specimen, Richardson, M. H., 443; the Brandt method of pelvic massage, 474; suprapubic hysterectomy, Eastman, J., 553; the conservative surgery of the female pelvic organs, Polk, W. M., 573; the conservative treatment of the female pelvic organs, 574; pelvic inflammations, Wheeler, L., 615.
- Gibney, V. P.** A case of myositis ossificans, with multiple exostoses, 43; the Lorenz treatment of hip disease, 219; excision of the hip, 219.
- Gilbert, D. D.** The production of vaccine virus, 434, 444.
- Girl.** The effect of climate and environment on the New England girl, Achorn, J. W., 58.
- Gladstone.** Mr. Gladstone's tribute to Sir Andrew Clark and the medical profession, 579.
- Glasgow, W. C.** A new and distinguishing sign of latent aneurism of the aorta, 651.
- Goodell, W.** The conservative treatment of the female pelvic organs, 574.
- Goss, F. W.** Two cases of pulmonary congestion and oedema occurring during pregnancy, 336, 341.
- Gout.** American gout, 213.
- Grant, J. H.** Toxic effects after use of oil male fern (etheral) for tapeworm, 337.
- Green, C. M.** Obstetric case-blank, 98; four unusual cases; imperforate hymen with hæmatocolpos, mucous cysts of the vagina, recto-vulvar fistula, salivation of pregnancy, 358, 367.
- Greene, E. W.** Crystalline deposits in the urine, their causation and relation to renal diseases, 538, 560, 564.
- Greene, J. S.** The obscure origin and indeterminate course of acute infection, as illustrated by a case of malignant endocarditis, 567, 563.
- Greenhalge.** Inaugural address, 49.
- Greenleaf, R. W.** The Charles River in its relation to the etiology of intermittent fever, 353, 367.

- Hall, J. N.** "Sending patients away from home," 27; weight as a symptom in phthisis, 607.
- Hall, R. M.** Perforating wound of the heart, 431.
- Hamburg.** Recent sanitary improvements in Hamburg, 577.
- Hand.** A case of club-hand and club-foot, Sayre, R. H., 42.
- Hard Times.** Diseases due to hard times, 194.
- Harrington, F. B.** Right-sided, followed at an interval of two years by left-sided Fallopian pregnancy, with repeated operation, 6.
- Harrington, M. W.** Sensible temperatures, 652.
- Haven, G.** A case of puerperal septicæmia, 140, 142.
- Hay, G.** Removal of foreign body from the anterior chamber of the eye, 142.
- Hayes, M. C.** The vermiform appendix, 175.
- Heart-failure,** 499.
- Henry, F. P.** A clinical report of two cases of Raynaud's disease, 621.
- Hexter, C. A.** A critical review of the various theories of uremia, based upon original experimental observations, 497.
- Hibberd, J. F.** Annual address before the American Medical Association, 623.
- "Higher medical education,"** Ingalls, E. F., 51.
- Hinsdale, G.** The comparative rarity of phthisis in the highlands of Pennsylvania and the adjacent counties of New York, 651.
- Hindu system** of medicine and the secret of success in practice, 427.
- Hip.** The Lorenz treatment of hip disease, Gibney, V. P., 219; excision of the hip, Gibney, V. P., 219.
- Hogner, R.** Treatment of small-pox by non-admittance of the chemical rays of light, 35; on spermatorrhœa and incipient hypothyroidism of the prostate and a proposed method for its treatment, 439.
- Houston, J. A.** On the value of examination of the blood of the insane, 53.
- Hughes, C. H.** The nervous system in disease and the practice of medicine from a neurological standpoint, 624.
- Hyde, J. N.** The distribution of leprosy in North America, 571.
- Hydræmia.** Two cases of hydræmia associated with abdominal distention in the fetus, Townsend, C. W., 139, 142.
- Hydrocele.** The radical cure of hydrocele, Gavin, M. F., 210, 213; the open incision in uncomplicated cases of hydrocele, Clendenin, P., 440.
- Hygiene, Health and Boards of Health.** Report of the Massachusetts State Board of Lunacy and Charity, 72; a sanitary sermon in diagram, Sundberg, J. C., 77; sanitary hygiene, a scheme, 170; a new bill for the establishment of a national bureau of health, 247; recent investigations of the British Government upon the influence of certain trades or occupations upon health, 294; recent progress in public hygiene and preventive medicine, Abbott, S. W., 337; the Charles River in its relation to the etiology of intermittent fever, Greenleaf, R. W., 353, 367; the sewerage system in Fitchburg, 425; chemical, physical and bacteriological studies of air over decomposing surfaces, with especial reference to their application to the air of sewers, Abbott, A. C., 569; the effect of sewer-gas in the production of disease, Jacobi, A., 570; sewer-gas as a cause of throat disease, or the effect of bad drainage on the throat, Robinson, B., 570; recent sanitary improvements in Hamburg, 577; retrogressive legislation in regard to Massachusetts boards of health, 578; annual report of the Boston Board of Health, 602.

- Hymen.** A rare form of the hymen, Draper, F. W., 142.
- Hypnotism.** Hypnotic suggestion in the cure of asthma, 350.
- Ichthyol.** A note on the use of ichthyol, Sinclair, 140, 141.
- Immigrants.** The foreign quarantine of immigrants, 327.
- Infectious Diseases.** A classification for infectious diseases, Thomson, W. H., 551.
- Ingalls, E. F.** "Higher medical education," 51; four years' course at Rush Medical College, 103.
- Insane.** The supervision of the insane in New York, 195.
- Insurance.** Foot-ball vs. insurance, Wells, G. W., 76; sanitary insurance, a scheme, 170.
- Intermittent Fever.** The Charles River in its relation to the etiology of intermittent fever, Greenleaf, R. W., 353, 357.
- Jack, E. E.** Thrombosis of the central artery of the retina with unusual features, 312.
- Jackson, H.** A review of ninety-two cases of diseases of the heart observed in the out-patient department of the Boston City Hospital, 111.
- Jacobi, A.** The effect of sewer-gas in the production of disease, 570.
- Jacoby, G. W.** A case of progressive muscular atrophy of the perineal type, 392.
- Japanese girls in boxes,** 656.
- Johnson, A. B.** A case of neuralgia of the great occipital nerve, with symptoms of a destructive lesion of the cervical sympathetic, 392.
- Johnson, F. W.** Six cases of extra-uterine pregnancy, 256, 265.
- Joslin, E. P.** Pathology of diabetes mellitus, 309, 330; clinical note-taking, with a list of four hundred and ninety-nine medical cases shown to the third class of the Harvard Medical School, 415.
- Keefe, J. W.** Twelve consecutive and successful operations for appendicitis, 282, 306.
- Keen, W. W.** The pleasures and pains of a physician's life, 126; amputation of the entire upper extremity (including the scapula and clavicle) and of the arm at the shoulder-joint, 565.
- Kenyon, C. G.** Annual address before the Medical Society of the State of California, 441.
- Keyes, E. L.** Nephritis in its surgical aspects, 572.
- Knapp, P. C.** Report on diseases of the nervous system, 62, 94.
- Knight, F. G.** Shall anything be done by legal authority to prevent the spread of tuberculosis? 630.
- Lane, L. C.** A reminiscence of the Nicaraguan filibusters, 50.
- Larynx.** Twenty-six cases of intubation of the larynx, Day, F. L., 356; address before American Laryngological Society, Delavan, D. B., 556; extirpation of the larynx, Carmalt, W. H., 600.
- Leach case,** 382, 390.
- Legal Medicine.** Recent progress in legal medicine, Draper, F. W., 313.
- Legislation.** Proposed legislation for the better protection of the community against quackery, 478; "The Medical Registration Bill in the Massachusetts Legislature," 527; the rise and fall of the licensed physician in Massachusetts, Fitz, R. H., 529; the Medical Registration Bill, Gay, G. W., 551; retrogressive legislation in regard to Massachusetts boards of health, 573; the legislative control of medical practice, Fitz, R. H., 581, 609, 637.
- Leprosy.** The distribution of leprosy in North America, Hyde, J. N., 571; the contagiousness, prophylaxis and control of leprosy, White, J. C., 571; resolution before the Congress of American Physicians and Surgeons, 589.
- Leucocytois.** The diagnostic and prognostic importance of leucocytois, Cabot, R. C., 277, 292.
- Litholapaxy.** Two cases of litholapaxy, Allen, G. W., 383, 388.
- Litholaprist,** 50.
- Liver.** The rôle of alcohol in the causation of cirrhosis of the liver, 324.
- Longevity.** External indications of inherited longevity, 128.
- Loomis, A. L.** The influence of animal experimentation on medical science, 585.
- Lorenz treatment of hip-disease,** Gibney, V. P., 219.
- Male Fern.** Toxic effects after use of oil male fern (etheral) for tapeworm, Grant, J. H., 337.
- Malignant Tumors.** The treatment of inoperative malignant tumors by the toxins of erysipelas and prodigiosus, Coley, W. B., 598.
- Mallory, F. B.** Letter from Prague, 77.
- Manley, T. H.** A bloodless operation for hemorrhoids, 114.
- Martin, F. C.** The production of vaccine virus, 479.
- Mason, A. L.** Second attacks of typhoid fever in adults, two cases, 180.
- Massachusetts.** A bill to provide for the registration of physicians and surgeons in the State of Massachusetts, 426.
- Materia Medica and Therapeutics.** Changes in the Pharmacopoeia, 25; pharmacy, therapeutics and credulity, Cash, 50; the action of permanganate of potash in rendering morphia inert, 124; a note on the use of ichthyol, Sinclair, A. D., 140, 141; remarks on the therapeutic use of sheep's thyroids and of other organic extracts, Putnam, J. J., 153, 168; relaxation as a curative agent, Cail, A. P., 331; toxic effects after use of oil male fern (etheral) for tapeworm, Grant, J. H., 337; saturated solution of potassium permanganate in the treatment of chronic ulcer, Waughop, F. R., 467; treatment of diphtheria by frequent small doses of biniodide of mercury, 474; the effect of ether and chloroform on the kidneys, Wanderlich, 477; the treatment of tuberculosis by the subcutaneous use of the chloride of gold and sodium with the iodide of manganese, Boardman, W. S., 492; the over-zealous therapeutician, Stokvis, 526; report on therapeutics, Williams, F. H., 543.
- Maxillary Sinus, surgery of the,** Bryan, J. H., 590.
- McCullum, J. H.** Remarks on diphtheria, 107, 115.
- Measles.** Measles and theology, 427; the first epidemic in Samoa, Davis, S. H., 605.
- "Mental Cure."** What "mental cure" is, Whipple, L. K., 148.
- Millard, P. H.** Another four years' course, 27.
- Mills, C. K.** Relation of infectious processes to mental disease, 592.
- Mind.** On the value of examination of the blood in the insane, Houston, J. A., 53; report of the Massachusetts State Board of Lunacy and Charity, 72; what "mental cure" is, Whipple, L. K., 148; the supervision of the insane in New York, 195; report on mental diseases, Stedman, H. R., 494, 517; relation of infectious processes to mental disease, Mills, C. K., 592.
- Minot, K.** Observations on cases of fibroid tumor of the womb, 406, 419.
- Morphia.** The action of permanganate of potash in rendering morphia inert, 124.
- Morphology as a factor in the study of disease,** Allen, H., 567.
- Morrill, F. G.** Cases of acute pneumonia in children, 541.
- Morris, M.** The dermatology of to-day, 298.
- Morris, R. T.** Infectious appendicitis, 133.
- Morse, J. L.** Bacteriological cultures from a case of puerperal septicemia, 140, 142; a bacteriological study of four hundred cases of inflammation of the throat occurring in diphtheria and scarlet fever, with especial reference to pathogenesis, 162, 182.
- Mumford, J. G.** Compound fractures, 463, 471.
- Muniz collection of skulls,** 402.
- Myxodema.** A case of myxodema treated by thyroid extract, Cowles, W. N., 167; four cases of myxodema treated by thyroid extract, Shattuck, F. C., 177, 191; a case of myxodema, Putnam, J. J., 190; a case of myxodema, Bell, R. E., 364.
- Nails.** Nail-biting, 22.
- Negro.** The solution of the negro rape problem, 126.
- Nephritis in its surgical aspects,** Keyes, E. L., 572; the bacteriology of nephritis, Sternberg, G. M., 573.
- Nervous System.** Anomalous cases of general paresis, Fisher, E. D., 15; discussion on the relation of syphilis to general paresis, Peterson, F., and others, 15; report on diseases of the nervous system, Knapp, P. C., 62, 94; ovariectomy for nervous disease, Edes, R. T., 105; gliosarcoma of the basal ganglia, 117; sub-acute unilateral bulbar palsy, with autopsy, Wiener, A., 118; the pons-medulla focculus triangle as a tumor site, with pathological findings, Newton, R. S., 418; syringomyelia, central glioma of the spinal cord, with spontaneous central hemorrhage, Dana, C. L., 119; a case of infantile cerebral spastic diplegia, Peterson, F., 120; deafness due to a foot-ball injury, Corning, J. L., 120; a case of acromegaly, Parsons, R. L., 120; ergot in the treatment of periodic neuralgias, Thomson, W. H., 121; diphtheritic paralysis, 123; recent observations on the functions of the thyroid gland and the relations of the enlargement to Graves's disease, also remarks on the therapeutic use of sheep's thyroids and of other organic extracts, Putnam, J. J., 153, 168; case of fatal hemorrhage from the left lateral sinus caused by a blow on the jaw, 201; Pott's paraplegia, Whitman, R., 218; electrical reactions and their value in diagnosis and prognosis, Starr, M. A., 317; a case of progressive muscular atrophy of the perineal type, Jacoby, G. W., 392; a case of neuralgia of the great occipital nerve, with symptoms of a destructive lesion of the cervical sympathetic, Johnson, A. B., 392; a case of hysteria with peculiar epileptoid attacks, Booth, J. A., 393; electrical reactions and their value in diagnosis and prognosis, 393; tapping of the lateral ventricles, Frank, 401; a case of amyotrophic lateral sclerosis, Brown, C. H., 496; a case of progressive muscular dystrophy, Wiener, A., 496; a critical review of the various theories of uræmia, based upon original experimental observations, Herter, C. A., 497; railway spines and surgeons, 523; the influence of infectious processes on the nervous system, pathology and etiology, Putnam, J. J., 591; the therapeutics of infectious processes of the nervous system, Deroom, F. X., 594; cases of traumatic headache, Folsom, C. F., 621, 641; the nervous system in disease and the practice of medicine from a neurological standpoint, Hughes, C. H., 624.
- Newell, O. E.** The intermittent rapid dilatation of urethral stricture, 389.

Original Articles.**CASES OF ABDOMINAL SURGERY OCCURRING IN THE PRACTICE OF DR. J. COLLINS WARREN AT THE MASSACHUSETTS GENERAL HOSPITAL DURING THE WINTER OF 1893.**

REPORTED BY CHARLES L. SOUDDER, M.D.

THE following cases are reported in order to show the miscellaneous character of abdominal cases which come to a general hospital for treatment, and in order to illustrate the general method of dealing with cases of this class.

CASE I. Solid tumor of the ovary; laparotomy; recovery.

A domestic, single, forty-three years of age, entered the hospital November 2, 1892. For the last twelve years she has suffered from epileptic seizures, which she describes as "giving warning," and affecting the right side mainly. Her general health has otherwise been good. The catamenia have been regular, but ceased two months ago. She noticed some soreness of the abdomen upon bending over about two months ago, and not until that time did she notice any enlargement. She has had no pain, but has experienced a feeling of weight and dragging when walking about. The patient is poorly nourished, and there is a slight suggestion of cancerous cachexia. On examination, the abdomen was found to be somewhat distended with ascitic fluid, and a large, very hard and nodular tumor was felt, extending three inches above the umbilicus and down to the pubes. It was quite movable, and could be easily pushed from side to side of the abdomen. On vaginal examination, the uterus was found small, movable and not connected with the growth. The lungs and kidneys were normal. The tumor was regarded as probably malignant, and attached to the omentum. It was thought advisable to perform an exploratory operation.

An incision, four inches in length, was made below the umbilicus, which disclosed a hard, nodular mass of a whitish color floating in ascitic fluid. The incision was enlarged to two inches above the umbilicus, and the tumor was delivered, and found to be attached to the left broad ligament. The pedicle was long and thin, and easily tied with a Staffordshire knot. The tumor, on removal, was found to be about the size of a child's head, and to weigh eight and one-half pounds.

Examination of the other ovary showed it to be about twice its normal size, hard and nodular, resembling somewhat in this respect the diseased ovary.

Patient made a good recovery, temperature not rising above 100° F., although the evening of the operation she sat up in bed, and had several epileptic seizures during her convalescence. The stitches were removed on the thirteenth day, union being perfect. The catamenia appeared on November 28th, immediately after one of the seizures.

She was discharged from the hospital four weeks and four days after the operation.

The following is the report of the microscopical examination of the tumor by Dr. W. F. Whitney: "A large globular growth, the size of the head, firm, not covered by peritoneum, and united to a fragment of the Fallopian tube. Microscopic examination showed it to be made up of fibrous tissue, with here and there a few bundles of unstriped muscular fibre. Fibro-myoma. There were no cysts in any part of the tumor."

CASE II. Cyst of the ovary; laparotomy; recovery.

Age forty, unmarried. Catamenia regular, painless. For four years the abdomen has been enlarging. There has been constant pain in the right side. Upon examination, a symmetrical abdominal tumor was found, which was dull on percussion and not tender. Vaginal examination found the uterus drawn well up.

Operation, by a median abdominal incision, disclosed a cyst of the right ovary. There were no adhesions present, and the cyst was easily delivered, and its pedicle clamped and tied with a Staffordshire knot. A small cyst was found upon the left ovary about the size of a small cherry, which was touched with the actual cautery; the left ovary, however, was not removed. The abdominal wound was closed without drainage.

The patient made a good recovery.

Dr. W. F. Whitney's microscopical diagnosis was a multilocular cysto-adenoma.

CASE III. Salpingitis, circumscribed serous peritonitis; laparotomy; recovery.

A woman thirty-two years old, married. Fairly well developed and nourished. Rather anæmic, with a feeble pulse. Catamenia irregular and excessive. Miscarriage five years previous to the operation. Patient has had pain in the left iliac region for a year and a half, which has been continuous, and during the past two months accompanied by vomiting and fever.

Examination discovers a marked fulness in the left iliac region. Dulness and tenderness exist over this area of fulness. Vaginal examination finds the cervix drawn up and fixed under the symphysis pubis, the vaginal vault hard and firm everywhere, the uterus not differentiated; no fluctuation made out.

Operation by a median abdominal incision in the Trendelenberg position.

The tumor was found adherent to the anterior abdominal wall for about six inches. Upon freeing the tumor, the left iliac fossa was found to contain a thin-walled cyst, which was easily ruptured, giving escape to one pint of thin, serous fluid. Below and behind this cyst was a tumor the size of the fist, adherent to the uterus and posteriorly to the sacrum. Several large glands were felt at the sacral promontory. This deeper tumor was aspirated, and eight ounces of creamy pus evacuated. The sac of the tumor was opened; its interior thoroughly cleansed and drained by glass drainage surrounded by gauze. Incision partially closed. Recovery uneventful.

CASE IV. Congenital hernia of the liver; reduction of the hernia; recovery.

The paternal grandparents, as well as the father of the little patient, are living and in good health. The mother is well, but not robust. Her mother is living, but her father died of consumption. The mother of the patient was married five years ago. Her first child was born three years ago, but died at the age of four months of cholera infantum. It had no deformity, and was in previous good health.

The second child was born November 14, 1892. Labor began at 6 P. M. of the 18th, and was completed at 10 A. M., and was normal in every respect. Dr. G. W. Nickerson, of Stoneham, Mass., who was her physician, states that he was surprised to see, after birth of the head and shoulders, a tense, bladder-like tumor come popping out, after which followed the lower extremities. He states: "I was puzzled at first to make out what it was, but, seeing that it was covered by an expansion of the umbilical cord, concluded that

it must be a hernia." The child was sent that afternoon to the hospital, and was operated upon by me the next morning, when it was about twenty-four hours old. On inspection, the child was otherwise well formed, but thin and with a somewhat wrinkled face. It did not look strong. At the umbilicus was seen the cord, which was greatly distended at its point of insertion into the abdomen, forming a tumor about six and one-half centimetres in diameter. The coverings of the cord were inserted into a raised rim of skin, and were opaque, so that the contents of the hernia could not be determined (Fig. 1).

There was also a moderate-sized right inguinal hernia.

FIG. 1.

The child was etherized, and a hasty attempt having been made to render the field of operation aseptic, the sac was opened, and was found to contain the liver, which seemed to be situated wholly external to the abdominal cavity. It was with some difficulty that the myxomatous tissue of the cord was separated from the surface of the liver, as it appeared to be adherent in several places. The umbilical vein and the two hypogastric arteries having been tied and cut, the cord was removed. The umbilical ring was slightly enlarged by an incision, and, with some manipulation, the liver was finally pushed through the opening into the abdominal cavity. A small amount of ascitic fluid escaped when the sac was first opened. The separation of adhesions from the liver caused a slight hemorrhage, which was checked by pressure. The wound was brought together by four or five strong silk stitches. The infant suffered somewhat from shock. There was, however, no sign of peritonitis after the

operation, and it took its nourishment well during convalescence. The food consisted of a mixture of cream and water.

The stitches ulcerated somewhat, and were removed during the first week, in consequence of which the edges of the wound separated at one point, and the liver could be seen. The edges were, however, approximated by *crêpe d'isse* and collodion, and the wound had healed at the end of two weeks, when the baby was taken home to be nursed by its mother.

The child has done well since, and at the time the second photograph was taken it was about four months old (Fig. 2).

There is no umbilical hernia at present — one year

FIG. 2.

after the operation. The child was a sufferer from eczema, but now enjoys excellent health, and has developed rapidly.

CASE V. Ruptured cyst of the broad ligament; contents evacuated; treated openly; recovery.

A woman was admitted to the medical side of the hospital in 1889 with tubercular peritonitis. Her general health had improved since her former visit to the hospital, and ten days ago she complained of pain in the left side of the abdomen. At no time has there been any vomiting, and a normal movement of the bowels resulted after the use of salts. The abdomen was slightly distended; and in the left lumbar and iliac regions was a tumor the size of two fists, over which there was dulness and slight sensitiveness. The uterus by vaginal examination was low down, the posterior and left lateral cul-de-sacs being filled by a soft mass which seemed to surround the cervix which moved with the tumor. The urine was normal.

Operation.—The Trendelenberg position. A median abdominal incision. Some ascites present. The intestine and omentum were found adherent to a ruptured, thin-walled cyst having its origin in the left broad ligament. The cyst was further opened and its interior rendered dry. It being impossible to enucleate the cyst, it was left *in situ*, being sutured to the abdominal wall. In the left lateral cul-de-sac was found a second smaller cyst, which was likewise ruptured and drained by means of a glass drainage-tube.

The patient made a good recovery and was discharged from the hospital about three weeks after the operation, a small sinus remaining.

CASE VI. Abscess following appendicitis; operation on the fourth day; recovery.

A man who had always been well was attacked suddenly after breakfast by pain in the right iliac fossa. Through that day there was some nausea. Two days later there was a slight rise of temperature, and vomiting was present. Four days later the temperature rose to 101.4°, the pulse to 140. A tumor presented in the right iliac fossa, a half inch below McBurney's point, about the size of a lemon; dull on percussion and sensitive.

Operation.—An incision parallel to Poupart's ligament opened a circumscribed abscess cavity, in which was found the appendix twisted under the cæcum. This was removed, the abscess cavity thoroughly cleansed with boiled water, a rubber drainage-tube surrounded by iodoform gauze placed in the abscess cavity, and the wound partly closed.

The patient made a good recovery. Two months after the operation there was a slight tendency to hernia at the seat of the operation. The patient had gained ten pounds in weight and complained of no pain or any other trouble.

CASE VII. Abscess following appendicitis; operation on the seventh day; removal of appendix; recovery.

A man who had had each year for several years two or three attacks of vomiting attended by slight constipation, and who had never had with any of these attacks pain, was suddenly seized with pain in the right iliac fossa. The temperature rose to 99.5°. There was some vomiting. There was a movement of the bowels after calomel and a rectal enema. The temperature rose to 103.2°, the pulse to 120 upon the fifth day. Upon entering the hospital on the seventh day of the disease, it was stated that from the sixth day vomiting was constant. The abdomen was not distended, but the abdominal muscles were rigid. The most tender point upon the abdomen was one and a half inches above the anterior superior spine, but there was general tenderness through the whole right loin. A slight bulging was detected upon rectal examination upon the right side.

Operation.—An incision parallel to Poupart's ligament found the subperitoneal tissues not oedematous. A circumscribed abscess cavity was opened, the appendix found and removed, the cavity irrigated with boiled water, and two tubes for drainage (surrounded by iodoform gauze) were inserted.

The patient made a good recovery. Six weeks after the operation he was reported as in excellent condition.

CASE VIII. Appendicitis; operation; recovery.

This patient was a boy who was sent to the hospital with a history of several days' illness, all the symptoms of which pointed to an appendicitis. Although

the patient presented slight dulness on percussion in the region of the right iliac fossa, there was no well-marked cake. He was seen repeatedly by the surgeons of the hospital in consultation. All the symptoms present led to a delay of the operation, and it was supposed up to the fourth day of his presence in the hospital that he would recover without operation, but upon this day there was a sudden rise of temperature and operation was decided upon. The usual incision parallel to Poupart's ligament was made. Oedematous tissue was seen before opening the peritoneum. The appendix was found under the inferior edge of the cæcum, perforated at its middle and lying in a very small abscess cavity, which contained beside purulent and faecal material, a concretion. The omentum and mesentery near by were gangrenous. The appendix was ligated one-third of an inch from the cæcum and removed. The abscess cavity, being circumscribed, was thoroughly irrigated with boiled water. It was found that the pus lay between coils of intestine some distance from what appeared to be the only abscess cavity. A large tube was placed in the bottom of the abscess cavity and two smaller tubes extending in opposite directions, all the tubes being surrounded by iodoform gauze.

Six weeks from the operation the boy was discharged well.

These three cases were the only cases of appendicitis occurring during a winter service. It is perhaps worth mentioning that in the spring service of a similar length, Dr. Beach had under his immediate care a large number of cases of appendicitis. This fact raises the question of the possibility of the period of the year being a factor in the etiology of this disease.

CASE IX. Double tubercular salpingitis and peritonitis; laparotomy; relieved.

A woman who had had pleurisy one year previous to her entrance into the hospital gave a history of profuse flowing for two months. She presented upon examination a resistant mass in the region of the right tube. The uterus was in fairly good position and movable. The cervix was slightly lacerated and hyperplastic. Posteriorly to the uterus was a mass the size of the closed fist. This corresponded with the mass felt upon external examination. The urine was 1,013, acid, high in color, contained a trace of albumen, some red blood cells and a few epithelial cells.

Operation.—Trendelenberg position. An incision four inches long in the median line. Some ascites present. The uterus was very large. The broad ligaments and tubes were found studded with military tubercles. The tubes themselves were enlarged and thickened. Upon the left side there were no adhesions and the tube was removed without difficulty. Upon the right side the tube was the size of a fist, and was adherent to the bowel above. Upon separating these adhesions both tube and ovary were removed. A small amount of puriform fluid escaped into the abdominal cavity upon the removal of the tube. The abdomen was thoroughly flushed with boiled water, dried and drained by a glass drainage-tube in the posterior cul-de-sac. The abdominal wound was closed, leaving the glass tube projecting at the lower end of the incision. This patient made a long and slow recovery, having a hectic temperature and some stomatitis. By careful nursing, and upon warm days by being taken into the open air, she eventually recovered so as to leave the hospital in a fairly good condition.

tion, feeling that she had been improved by the operation, her stay in the hospital having been some three months.

It seems that in a great many cases the careful nursing and the out-of-door exposure contributes much to the recovery of these cases.

CASE X. Probable carcinoma uteri; rupture into the abdominal cavity; laparotomy; drainage; death from shock.

A woman, married, having three children, had passed the climacteric three years ago. She had a foul leucorrhœa, and at times a bloody serous discharge from the vagina. She suffered from pain over the pubes and difficult micturition. Upon examination, the uterine canal measured five inches. A small greenish-brown mass was found projecting from the cervix. This was removed some six months previous to the present entry into the hospital, since which removal she has grown weak, has lost flesh, and has occasional chills accompanied by nausea. Her feet and hands were cold, and she presented a general cachectic appearance. The pulse was 112. The temperature at night ranged from 100° to 101°. The uterus was curetted and thoroughly cleansed with corrosive sublimate.

Finding the patient was losing ground, it was decided to do a median abdominal section in order to determine the extent of the disease, and if possible to remove it. Accordingly, in the Trendelenberg position, the operation was done. The omentum was found adherent to the bladder, and the intestines adherent to the fundus of the uterus. On breaking up these adhesions, a cavity containing six ounces of pus was opened a little to the left of the fundus which communicated directly with the cavity of the uterus. The bottom of this cavity was filled with greenish sloughing tissue. The cavity was irrigated and packed with iodoform gauze. A suprapubic glass drainage-tube was placed in position. A strip of gauze was passed through the cervix to secure more thorough drainage.

The patient died of shock some hours after the operation.

CASE XI. Double ovarian cyst; laparotomy; recovery.

A woman thirty-six years old, always well, had been married for fourteen years. She has had no children. The catamenia have always been regular and painless. An enlargement of the abdomen was first noticed seven years ago. Never at any time has there been pain. Her general health has been good.

Physical examination showed general abdominal enlargement. No enlarged veins were seen upon the abdominal wall. Circumference of abdomen at the umbilicus was forty-five inches. Vaginal examination found the cervix high and crowded forward. A hard and resistant mass was felt in the posterior cul-de-sac.

Operation.—A median abdominal incision. The omentum was found adherent to the anterior abdominal wall. A pearly-white cyst wall presented, was aspirated, discharging a coffee-colored fluid. The weight of the fluid was twenty-eight pounds. The cyst, after the evacuation of the fluid, was found to originate from the right ovary. The tumor was removed by Staffordshire knot and cauterization. No drainage.

Eight days after the operation phlegmasia alba dolens of the left leg appeared. One month later the swelling had entirely disappeared from the left leg and she was discharged from the hospital, seven weeks after the operation.

Pathological report by Dr. W. F. Whitney: "Multilocular cystoma, to which a small piece of the ovary was attached."

Remarks.—The phlebitis which occurred in this case did not have any apparent septic origin. The patient was kept still in bed for the time mentioned above, in order to avoid the danger of embolism, which occasionally occurs with such inflammatory disturbances.

CASE XII. Intra-ligamentous ovarian cyst; laparotomy; recovery.

Two months ago a woman first noticed an enlargement in the lower abdomen, extending over to the left side. This tumor gradually and painlessly increased in size. The tumor was dull upon percussion, and fluctuating. The vaginal examination found the uterus pushed backward and to the right.

Operation by median abdominal incision discovered a cyst in the broad ligament containing about a quart of brown fluid. The intestines were adherent posteriorly. After freeing these adhesions, an attempt was made to enucleate the sac of the cyst, which proved futile on account of the dense adhesions to the sacrum posteriorly. The right ovary was removed. The cyst sac was stitched to the anterior abdominal wall, drained by glass drainage and gauze. A sinus formed, and was packed with iodoform gauze, gradually closing without untoward symptoms. The patient was discharged from the hospital with a very small sinus properly healing.

CASE XIII. Ovarian cysto-adenoma; laparotomy; recovery.

A woman of good family history and good previous personal history one year ago noticed an enlargement of the abdomen, which during the past two months had rapidly but painlessly increased. During the past six weeks there had been considerable flowing. The patient was well developed and well nourished, and the examination disclosed a swelling of the abdomen extending above the umbilicus, dull upon percussion, fluctuating and not tender. Vaginal examination found the uterus immovable and small. The posterior cul-de-sac was distended with an obscurely fluctuating mass, which was not tender. The os was rather soft and patulous.

Operation by median incision found a glistening cyst wall, which contained a chocolate-colored fluid, nine quarts by measure. Small cysts were found anteriorly attached to the anterior wall of the larger cyst. The tumor rose from the right ovary, which, with the cyst wall, was removed by clamp and canter. The left ovary was found enlarged and moderately cystic, and was not disturbed. The uterus was heavy and ante-flexed. The wound was closed in the usual fashion by interrupted sutures without drainage.

Pathological report by Dr. W. F. Whitney: "A large cyst, smooth-walled, with but few adhesions, to which a very much elongated Fallopian tube was attached. The fluid was ropy, dark reddish in color, specific gravity 1.026, and contained abundant blood-corpuscles, and also enlarged epithelial cells (many with numerous granules). Diagnosis, cysto-adenoma of the ovary."

(To be continued.)

THE Richmond City Hospital has been purchased by the College of Physicians and Surgeons of that city for \$18,489.39.

THE PREVENTION OF TUBERCULOSIS.¹

BY HERMAN F. VICKERY, M.D.,

Physician to Out-Patients, Massachusetts General Hospital; Instructor in Clinical Medicine, Harvard University.

THE official statistics of the State of Massachusetts for the five years, 1886-1890, set the total number of deaths from typhoid fever for that period at 4,391; from diphtheria and croup, at 8,855; from pneumonia, at 17,378; and from phthisis, at 28,868. With regard to relative fatality, diphtheria held the sixth rank in 1881, but in 1890 the eleventh. Likewise typhoid fever, which was fourth in bad pre-eminence twenty years before, was surpassed in 1890 by no less than fifteen rivals. The encouraging results which have thus attended efforts at purification and isolation in these two infectious diseases reflect credit upon the medical profession, and they stimulate the expectation that similar efforts with regard to another infectious and contagious disease will prove equally advantageous. As yet no advance seems to have been made. Phthisis remains the most deadly of all diseases. In the number of victims it claims, it was the first in 1881; and in 1890 it remained still the first. There had, indeed, been some improvement, taking the State as a whole; for in 1890, the ratio of deaths from phthisis to the total mortality was 13.30 per cent., the least of any year recorded up to that time, while in 1881, the ratio was 16.14 per cent. But Suffolk County showed no such change, its ratios being 16.39 per cent. in 1881, and 15.59 per cent. in 1890.

Lawrence F. Flick² finds that Philadelphia has been more fortunate. From 1881 to 1891 the percentage of the whole mortality in the city due to phthisis sank from 14 down to 11. Hence it will hardly be proper for us to try wholly to explain the slow improvement in Boston by a reference to the overcrowding and foreign immigration which are presumably common to both cities.

"Theoretically, with our present knowledge," says Dr. Baker, Secretary of the Michigan State Board of Health, "consumption, which still is the most important cause of mortality, is now, next to small-pox, one of the most easily preventable diseases. The next quarter of a century should see it lessen in importance as a cause of deaths, until it takes its place alongside small-pox."³

In the five years 1886-1890, while the above-mentioned 28,868 persons died of phthisis in Massachusetts, small-pox killed 19.

It is the object of this paper briefly to review the etiology of phthisis, and to contribute in some degree to a more general and united effort on the part of our Society in the prevention of the disease.

With regard to its causation, it is not improbable that Koch's demonstration in 1882 of the power of pure cultures of tubercle bacilli to cause tuberculosis diverted the attention of the profession for a time too far from the important factor of hereditary and acquired predisposition to the disease. Even weeds must have soil to grow in. This constitutional side of the question has been newly asserted by Aviragnet,⁴ Koster,⁵ and Wolff;⁶ while Gärtner⁷ believes that the results

of his experiments justify him in asserting that the disease itself is hereditary, that human mothers may directly give a fetus tubercle bacilli.

We cannot forget the influence of climate on the development of the disease, powerful for good or ill. Solly's experience is impressive.

"In Colorado,"⁸ he says, "to which my personal observations upon the influence of the altitude have been mostly confined, the native population is too small and youthful to gather any statistics; but living as I have done for the past sixteen years among a people of whom perhaps thirty per cent. came to the country with tuberculosis, and not a few of whom live under unhygienic conditions in crowded lodgings, and where free expectoration is carelessly practised, I know of only four cases of phthisis which could be fairly assumed to have originated in Colorado."

Granting, however, the influence of both climate and personal constitution upon the production of the disease, the bacillus tuberculosis is an essential factor; and probably no one doubts that its complete destruction would exterminate tuberculosis.

The ways in which the bacillus enters the human body are fairly well agreed upon. The raw⁹ milk of tuberculous cows may occasionally convey it into the stomach,¹⁰ but not very often.¹¹ The flesh of tuberculous animals if inspected (Jeffries, Nocard) is not very dangerous.¹² The tuberculous discharges of animals or human beings may infect others by direct inoculation into wounds or by contact with mucous membranes (dissection-wounds, coitus).¹³

The main source of danger, however, lies in tuberculous sputa or in the pus of scrofulous sores. The latter might conceivably be indirectly conveyed into the system because of lack of cleanliness. Sputum likewise may be deposited on the lips, hands, clothing and utensils of patients and thence carried to some healthy person; or the act of coughing may directly spray it into the mouth of a bystander. Any tuberculous material if thoroughly dried may be inhaled in the form of dust. This last is probably by far the most frequent way in which the infection is distributed. The number of bacilli in the sputa is enormous,¹⁴ and as Cornet and others have shown, even the walls of the room where a consumptive lives may become sources of infection.

The way, therefore, to prevent the spread of tuberculosis is evident enough; and it has been repeatedly enunciated by medical men.¹⁵ Behrens, for example, sums the matter up as follows: (1) the public should be enlightened; (2) sputum in public places should be minimized or rendered innocuous; (3) the streets should not be allowed to be dusty; (4) clothing, etc., and houses should be disinfected; (5) there should be public hospitals for the tuberculous; (6) tuberculous patients should not pursue vocations in which they might endanger others; (7) tuberculosis in cattle should be under governmental inspection and control. A corollary to these regulations is the compulsory report of cases of tuberculosis to the boards of health,

¹ Hare's Therapeutics, 1, 424.² Nocard: Ann. d'Hygiene, xxviii, 5, 1892.³ Ernst: Œuvre sur la Tubercule, 1890.⁴ Jeffries: Boston Medical and Surgical Journal, cxxv, 10, 1891.⁵ Philadelphia Medical News, April 1, 1893.⁶ Gärtner: supra cit.⁷ Nuttall: Ztschr. f. klin. Med., xxi, 3 and 4, 1892.⁸ Behrens: Hilderheim, 1891.⁹ Flick: Philadelphia Medical News, lxiii, 17, 1893.¹⁰ Porteous: Boston Medical and Surgical Journal, cxxix, 19, 1893.¹¹ Rochester: Philadelphia Medical News, September 2, 1893.¹² Baker: Hare's System of Therapeutics, 1, 510.¹ Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, November 15, 1893.² Philadelphia Medical News, May 14, 1892.³ Hare's System of Therapeutics, 1, 572, 1891.⁴ Gaz. Hebdom., xxxix, 36, 1892.⁵ Inaug. Thesis, Leyden, 1893.⁶ Münch. Med. Woch., xxxix, 39.⁷ Zeitschr. f. Hygien. u. Infectiouskr., xlii, 3, 1893.

just as in diphtheria or small-pox. Flick adds that interstate and international migration of consumptives should be restricted and regulated.

If all, or even the most important of these suggestions were persistently carried out, there can be no doubt that tuberculosis would be vastly less frequent than it now is. The benefit would be an increasing one, for many individuals who to-day are apparently well really carry in their bodies the seeds of tuberculosis, ready to germinate whenever the constitution becomes from any cause undermined. Pizzini¹⁶ and Spengler¹⁷ have recently shown how often the lymphatic glands — particularly the bronchial — contain tubercular bacilli in persons who have shown no symptoms of tuberculosis. This is in accord with the opinion expressed by Volland of Davos (Hamburg, 1891) that for adults the chief means of avoiding tuberculosis lies in care of the constitution.

In the long run, however, general, persevering, hygienic efforts must overcome this deadliest of diseases.

In concluding, I seek justification for rehearsing facts which are already so familiar to the members of this Society, in the apparent lack among us of systematic and united effort along the lines indicated. With few if any exceptions, we have doubtless all of us for years given advice to the victims of tuberculosis and their friends with a view to lessen the dangers of contagion; but why should not we as a Society engage more earnestly in this good work? Pennsylvania has a Society for the Prevention of Tuberculosis. "The society is formed for the purpose of preventing tuberculosis (consumption): (1) by promulgating the doctrine of the contagiousness of the disease; (2) by instructing the public in practical methods of avoidance and prevention; (3) by visiting the consumptive poor and supplying them with the necessary materials with which to protect themselves against the disease, and instructing them in their use; (4) by furnishing the consumptive poor with hospital treatment; (5) by co-operating with boards of health in such measures as they may adopt for the prevention of the disease; (6) by advocating the enactment of appropriate laws for the prevention of the disease; (7) by such other methods as the society may from time to time adopt."

This society is a noble one and I am proud to be a member of it. Yet with us here, it seems as if any increase in the number of societies were to be deprecated, and that our present society by exercising its proper functions might do beneficent work in this very line. Matters that suggest themselves as needing first to be done are:

(1) The drawing up, by a committee, of a tract suitable to leave in families where tuberculosis has entered. Properly worded, such a leaflet would add nothing to the sufferings of the sick, while it might be beneficial to them (hygiene, re-infection) and of priceless value to their friends.

(2) Co-operation with the Board of Health in appropriate measures.

(3) Agitation for the establishment of a public hospital for the consumptive poor.

LANDOUZY has been made Professor of Clinical Medicine and Therapeutics at Paris in succession to Hayem.

Clinical Department.

RIGHT-SIDED FOLLOWED AT AN INTERVAL OF TWO YEARS, BY LEFT-SIDED FALLOPIAN PREGNANCY, WITH REPEATED OPERATION.

BY FRANCIS B. HARRINGTON, M.D.,

Surgeon to Out-Patients at the Massachusetts General Hospital; Assistant in Surgery in the Medical Department of Harvard University.

MRS. M. J., thirty-two years of age, had been married for three years. Until two years ago had been well. She then became somewhat debilitated, and suffered from pelvic pain. Menstruation was slightly painful, and occurred every three weeks. She had never been pregnant.

In January, 1891, the menstrual period was delayed two weeks, when flowing came on with severe pain. The loss of blood was slight, but continuous.

This condition had existed, with increasing pelvic pain, for three weeks, when I first saw the patient. The abdomen was slightly distended and painful to the touch. Vaginal examination disclosed a mass on the right side of the pelvis as large as a lemon. This mass felt like a dilated Fallopian tube. The patient went to bed, was given opiates and vaginal douches. The flow of blood and pain gradually diminished, but returned on slight exertion. In six weeks' time from its first appearance the bleeding ceased. The pain, however, continued, and the tumor increased slightly in size. The continued abdominal tenderness and pain seemed to demand surgical treatment.

Laparotomy was performed May 15, 1891. The dilated right Fallopian tube was removed, together with a considerable amount of bloody fluid. The patient made a quick recovery.

Dr. Whitney makes the following report as a result of his examination of the specimen:

"The specimen consisted of about twelve centimetres of a Fallopian tube with an ovary close to the uterine end. The tube at the point of removal was increased in size, chiefly from thickening of the walls, which were very vascular. Close to this point a sudden dilatation began, forming an ovoid mass about eight centimetres in the direction of the tube, and nine centimetres in circumference, and beyond this it contracted somewhat to the fimbriated end, which was closed by adhesions and contained a few small cysts. The outer surface of the tube was rough and shaggy from adhesions.

"On opening the dilated portion it was found to contain a thin membranous-looking sac, loosely attached to the villous-looking inner surface of the tube, beneath which on one side were extensive infiltrations of blood separated by narrow fibrous portions. Within the sac lay a small reddish mass the size of a cherry-stone, on which was a curved differentiated portion recalling a very early embryo, the whole attached by a sort of string to the sac.

"Microscopic examination of this showed an amorphous granular mass, at one end of which was an accumulation of black pigment.

"The ovary was small, contained a few retention cysts, no evident corpus luteum.

"The diagnosis is a tubal pregnancy with early death of the fœtus (three to six weeks), hæmorrhage into the walls of the tube, but without rupture."

The process probably remained at a standstill from

the death of the foetus until the time of the removal, and the pain is to be referred to the peritonitis.

Two years later the patient had removed to the country, where she came under the care of Dr. E. S. Jack, of Melrose, who has kindly sent me the following notes:

"On March 24, 1893, the patient consulted me at my office, complaining of uncomfortable sensations over the lower abdomen. She was flowing.

"She feared that she had same trouble on the left side, which had been found on the right side two years before, as she felt very much as she did then.

"The examination was negative as far as determining the existence of extra-uterine pregnancy on the left side, although some tenderness was found.

"I next saw the patient on March 30, 1893. She was lying upon the sofa and complained of colicky pains, and a feeling of discomfort. There was considerable tenderness over the lower portion of the abdomen. The pulse was 80 and the temperature 99.4°.

"The patient was ordered to bed, and was given hot applications, hot douches and salines.

"Friday, the pulse was 76 and the temperature was 99°. More comfortable.

"Saturday, the pulse was 76 and the temperature was 99.6°. More comfortable, though flowing some.

"On Monday, April 3, 1893, there was more pain and tenderness, particularly on the left side. Vaginal examination showed considerable resistance on the left side.

"On Tuesday, the condition was the same. I demanded a consultation and advised operation.

"On Wednesday morning the patient felt decidedly better, but about 11 A. M. I was suddenly called. The patient had more colicky pain, and was faint, and suffered from blurring of vision. I advised immediate operation, to which the patient consented."

I saw Mrs. M. J. in consultation with Dr. Jack on April 5, 1893. There was a tumor in the posterior cul-de-sac toward the left side. The patient's condition was not bad, there was pain and some flowing.

I agreed with Dr. Jack in the diagnosis of probable extra-uterine pregnancy. As the immediate condition was not threatening, it was decided that we should delay operation until the first reappearance of severe pain or other urgent symptoms. On the following day there were signs of internal hæmorrhage.

It seemed unsafe to defer operation longer. An opening was made through the old line of incision. The abdominal cavity was reached with some difficulty, owing to the adhesions of the omentum. It was found to be full of dark blood and blood-clots. The dilated tube and the ovary on that side were excised. The blood and clots which lay among the intestines as high up as the diaphragm, were removed. The abdomen was closed without drainage. The patient made a good recovery, and now is quite well.

The patient's condition before the last operation did not seem especially bad. There had been some quite severe pain accompanied by giddiness. Neither the countenance nor the pulse gave a true indication of the large amount of the concealed hæmorrhage.

This case affords strong argument against delay. Waiting for extreme symptoms in extra-uterine pregnancy should be discouraged as it should be in case of appendicitis.

The question must arise whether the manipulation of the preceding day did not assist in producing the

hæmorrhage. Such a result is, of course, quite possible.

The liability to rupture of the mass by handling should always be borne in mind. An examination must try the strength of the tissue much more than any movements or acts of the patient.

Dr. Whitney makes the following report of the specimen removed at the second operation:

"The specimen was a pear-shaped dilatation of the Fallopian tube, which measured about eight centimetres in length, and about four centimetres at its greatest diameter at the fimbriated end, which was widely opened when received. The inner surface of this dilatation was quite smooth except in one or two places where there was a little roughness and a hæmorrhagic mass. The walls were thin and fibrous.

"With this was a rounded mass of blood-clot (which had come from the interior of the sac, probably), rough on its surface and containing in its centre a very thin, fibrous sac. There was also an embryo about four and one-half centimetres long (about the eighth week). The ovary was small, and contained a corpus luteum one and one-half centimetres in diameter.

"The diagnosis is a tubal pregnancy, with rupture through the fimbriated end of the tube at about the eighth week."

A CASE OF TUBERCULOUS PERICARDITIS WITH ENORMOUS EFFUSION; GENERAL TUBERCULOSIS; AUTOPSY.¹

BY EVERETT A. BATES, M.D., SPRINGFIELD, MASS.

W. J. J. P. was a marble-carver, fifty-eight years of age. His father had died at thirty years of "dropsy"; the mother at forty years of "consumption of the bowels," with cough as a persistent symptom in her illness; and a sister at twenty-eight years of the same trouble as the mother.

Mr. P.'s army experience resulted in a bullet-wound through right flank, followed by necrosis of the crest of ilium, with complete recovery in fourteen months.

Four years later than this, when thirty-three years of age, and coming on after exposure, he had an illness characterized by fever, loss of strength and flesh, cough and expectoration, lasting ten weeks, called "quick consumption," and terminating in a rapid convalescence and recovery.

There is a history of intermittent fever for four consecutive springs some twelve years since; but apart from the above, and a tendency to "lung colds" and temporary cough, the subject of this report had considered himself well and robust until three years ago the past spring, when he had a sickness, called by himself "grippe," associated with fever, debility, and cough without expectoration. He considered himself well in a month, after taking tonics, including cod-liver oil.

Again, eight months later, and a year before his last illness, similar attacks, all termed "grippe." But during these three years — noticeably the past year — there has been slight but gradual loss of flesh and physical vigor; and during the last five months there again developed cough, slight at first, but later hard and useless. He began to feel conscious of an afternoon temperature, and finally, from increasing weakness, gave up work February 8, 1893. During the

¹ Read at the meeting of the Hampden District Medical Society, September 19, 1893.

next ten days, slight dyspnoea and palpitation on exertion developed, with vague præcordial uneasiness, leading him to consult Dr. C. P. Hooker, with whom I saw the case March 18th, and by whose courtesy I am enabled to make this report.

The patient was a large, well-developed man, at this time fairly nourished. Skin sallow and dry; lips and nails a little dusky; very slight cedema of legs and ankles and of trunk, especially noticeable in the præcordial area; slight puffiness of eyelids. The jugulars pulsated and the veins of forehead were distended. Right semi-ventral decubitus was invariably assumed. The temperature varied from 100.5° to 102° in the afternoon, with a morning remission to normal. Pulse was 120, irregular and of fair strength. Respiration 26.

Inspection of chest showed præcordial fullness, with obliteration of intercostal spaces in this area. There was absence of cardiac pulsation or apex-beat. The præcordial fullness had for its upper boundary a line extending from the lower margin of the fifth rib, eight and one-half centimetres to the right of median line, to the junction of the right third rib with sternum, and thence in a gradual curve across sternum to second left interspace, downward through left nipple to fifth rib at a point thirteen and one-half centimetres from median line. With the patient sitting, this curve flattened perceptibly.

The heart-sounds—not abnormal in character—could be heard only, and faintly, in the second interspaces and the fifth and sixth interspaces left axillary line.

Dulness in the back was found below the eighth interspace scapular line on right, and eighth rib correspondingly on left. A few medium, moist râles above; lungs negative elsewhere. The liver was palpable below the costal border, with its lower line of flatness extending directly across abdomen.

The abdomen was full, not distended, with moderate dulness in flanks.

The urine was high-colored, loaded with urates, specific gravity 1026, no albumen, and no casts detected. No sputum could be obtained. The etiology of this affection was considered as, probably, tuberculous.

During the remaining six weeks of life the patient was comfortable; there was gradual loss of strength and moderate increase of plural and abdominal effusions, without apparent increase in pericardial.

Aspiration of the pericardium was considered, but not done, owing to the remarkable absence of distressing symptoms in spite of the enormity of the effusion.

During the last week delirium and anginal attacks at night developed; and the patient died suddenly on the morning of May 1st, while attempting to get out of bed.

The autopsy was performed eight hours after death. Rigor mortis present. Sternum prominent, slight general cedema, and subcutaneous tissues of trunk very watery. Head not opened. A considerable amount of clear serum escaped on opening the abdominal cavity. On removing the sternum, the pericardium presented as a large, distended bag, tense and nowhere adherent. The lungs were collapsed, and both pleural cavities contained a considerable amount of clear serum.

The outer surface of the pericardium showed numerous whitish elevations, some confluent and others dis-

crete. On incising the sac this pericardial layer was found to be greatly thickened, in portions as much as six or seven millimetres; the sac contained two litres of turbid, bloody serum. The cardiac layer of pericardium was everywhere thickened, and resembled so-called honey-comb tripe, and on section presented numerous opaque and yellowish points, and some yellowish masses scattered here and there. The heart itself, apart from a moderate degree of hypertrophy, was normal; its cavities were empty.

The pleura were nowhere adherent; the pulmonary layer was everywhere studded with grayish, opaque points up to a pin-head in size; the costal and diaphragmatic layers were free of these. The lungs, at the apices of the upper and lower lobes, showed old fibrous scars, and in other portions—as a rule, just beneath the pleura—many scattered and conglomerate tubercles. The air-passages contained reddish, frothy fluid. The bronchial glands and those in the anterior mediastrium were enlarged, caseous, and several perceptibly softened. The kidneys and spleen contained a few scattered tubercles. The pericardial fluid was not examined.

A CASE OF ACUTE HÆMORRHAGIC PANCREATITIS.

BY W. E. PAUL, M.D., BOSTON.

THE following case is reported as having some bearing on the subject of appendicitis. At the same time it illustrates the difficulty not infrequently presenting itself in making an ante-mortem diagnosis in abdominal affections. Moreover, cases of acute hæmorrhage into the pancreas are sufficiently unusual to warrant the report of an undoubted case however incomplete the data.

E. C., a robust farmer, aged sixty-two, suffered thirty years ago from severe intestinal symptoms. For five days death was expected, when something seemed suddenly to turn over in his stomach, and an intense epigastric distress, with vomiting, was relieved. The vomitus was black, but did not suggest blood.

Nine years later he suffered from symptoms similar in character but of less severity. A sense of discomfort was described as centering in the lower chest front and epigastrium. Every few days during the more recent years the distress has recurred, and during the past year its intensity has increased. For the past six years the patient has been confined to the house six weeks at a time. In the last summer of his life the attacks recurred daily, and required the patient to lie down.

Tuesday, October 3d, the patient felt more miserable, and at 11 A. M., Wednesday, had a decided pain in his epigastrium and under the lower half of the sternum, extending to each side perhaps as far as the nipples. He was looking forward eagerly to his dinner, feeling that the meal of pork and onions would relieve the distress and pain. He eat heartily, but immediately after finishing his meat was forced to leave the table and vomit the meal. Considerable retching followed, and the pain increased.

After about four hours the patient was visited, and was found pale, with a cold perspiration on the temples and hands; and suffering severely from most acute pain referred to the epigastrium and substernal region. The pulse was 70, of good strength, and the temperature was normal. Sulphate of morphia

(gr. $\frac{1}{4}$), with sulphate of atropia (gr. $\frac{1}{16}$), was given subcutaneously, and a few whiffs of chloroform added before the pain was at all relieved. The abdomen was moderately distended and tympanitic, but there was no tumor or special tenderness in the colic region. The bowels had moved daily, and operated twice freely on Wednesday morning. No gas had been passed since the pain set in. An enema was given, but nothing came away. Four hours later another enema was given without effect, though Epsom salts were added. The pain continued; and sulphate of morphia (gr. $\frac{1}{4}$), with sulphate of atropia (gr. $\frac{1}{16}$), was administered.

At 11 A. M., of Thursday, the pain was most severe. The pulse was 120, and the temperature subnormal. The feet were cold. Some dark fecal matter had been passed without gas. Occasional vomiting through the night had ceased about fourteen hours before death. The abdomen was now considerably distended and tympanitic. A diagnosis of appendicitis with perforation, was made. The question of ulceration from gall-stone, duodenal ulcer, internal obscure strangulated hernia, volvulus, and invagination was considered.

Dr. W. G. Reed, of Southbridge, was called in consultation, and the possible help of an operation caused a summons to be sent to Dr. Homer Gage, of Worcester. In the mean time, the patient failed rapidly, and at six o'clock Dr. Gage decided an operation was not warranted. The diagnosis he considered obscure, but inclined to the belief that there was an obstruction of the bowel, with perforation. The patient failed steadily, the abdomen swelled more and more, the breath becoming shorter and shorter, but he remained perfectly conscious. The death, thirty hours after the beginning of the attack, was apparently typical of acute peritonitis.

A partial post-mortem examination was granted. The abdomen was opened, and the omentum was found adherent from old peritonitis. The appendix was normal. The intestines were everywhere free, and showed no sign of peritonitis. Several stones were present in the gall-bladder. A soggy, heavy, enlarged pancreas was discovered, of a dark-red color: the organ was apparently loaded with blood.

Medical Progress.

RECENT PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D.

ARTHRORHISIS OF THE TIBIO-TARSAL JOINT FOR PARALYTIC CLUB-FOOT.

DRS. EDWARD SCHWARTZ and H. RIEFFEL report three cases of this operation with successful results.

The three cases were of adults, twenty-two, twenty-five and eighteen years of age, of paralytic equinovarus, all of whom had had previous operation or had worn apparatus, and in whom one lower extremity alone was paralyzed. The operation was by section of a tendo-Achillis, and in one case incision over the internal, and in the other two over the external surface of the ankle-joint, with section of the ligaments, erosion of the cartilages, and the bony parts being brought into apposition. In all the cases there was a firm bony ankylosis, and in all there was much improvement in walking.

The three methods of procedure are described by the authors, and consist of (1) by the anterior incision, as advocated by Albert, and later by his pupil Zinsmeister; (2) by incision above the internal malleolus, as recommended by Kirmisson; and (3) by the external incision, which is used by most surgeons. The relative value of these different procedures are carefully considered, as is also the method of the bone suture and the indications and contraindications for the operation. He gives the following conclusions:

(1) The operation is best done by external incision, as it is easier and does less injury to the important structures, without the necessity for osteotomy of the fibular; and also, if the bones of the tarsus are found to be the seat of extensive change, it gives the chance of changing the procedure at any part of the operation.

(2) It should be done in individuals having a flail foot, with whom walking is painful, and in whom apparatus has been found for any reason to be impracticable.

(3) It is also indicated in those irreducible paralytic club-feet which have resisted the use of tenotomy or of apparatus.

TREATMENT OF JOINT TUBERCULOSIS.¹

König calls attention to the three methods of treatment of this condition: (1) local treatment without the apparatus or an operation, (2) local treatment with medication by subcutaneous injection, (3) treatment by mechanical means. He inclines strongly to the mechanical and conservative methods, referring to a number of cases of spontaneous cure, and considers it wiser in a way to return to the old method of treatment, rather than to advocate too strongly active and early operative interference. He advises the use of continued extension and compression during the whole period of sensitiveness, the deformity to be overcome by extension, and later immobilization to be employed. When this is not sufficient he advises the use of injection of iodoform.

He reports 410 cases, 150 of which were treated by extension, and later by plaster for immobilization. In 50 there was an injection of glycerine and iodoform. Of 250 resections there was a mortality of 19 per cent. In 100 cases of resection of the knee in adults ranging in age from twenty to sixty-six, six died from the results of the operation and six soon after, four of these from septicæmia and two from tuberculosis. In 64 there was a complete cure; in 16 there was a sinus remaining; in eight amputation was performed.

He recommends a complete extirpation of the capsule in this joint, but does not advocate the resection of the hip-joint for coxitis, as recommended by Bardenheuer and Schmid, on account of the greater difficulty of removing all of these tubercular products. In suitable cases, when seen early, he recommends the removal of interosseous tubercular focus, but unfortunately it is not often possible, as they have usually broken into the joint when they first came under observation. In these cases he recommends, besides the erosion of this focus, the distension of the capsule with the mixture of glycerine and iodoform.

DIFFERENTIAL DIAGNOSIS OF NEW GROWTHS AND INFLAMMATORY ENLARGEMENTS OF BONE.²

Mr. Howard Marsh gives several examples of cases presenting enlargement of bone with the appearance

¹ Archiv. für Klin. Chirur., Band 44, Heft 3, p. 592.

² St. Bartholomew's Hospital Reports, 1892, vol. xxviii, p. 7.

of new growths, particularly malignant disease, all of which were found to be of an inflammatory character and contained pus. He cautions against the hasty diagnosis of malignant disease in these cases, and advises exploratory incision in all, and, if necessary, the microscopic examination with staining. As an aid to the diagnosis, he gives the following points to be observed: (1) age (all under twenty are usually inflammatory), (2) distinct history of injury, (3) the shape of the swelling, (4) the persistency of the swelling, (5) the rate of growth, (6) the condition of the skin and deeper soft parts over the swelling, (7) pain, (8) body temperature.

OSTEOMALACIA DURING PREGNANCY.³

Seligman reports a case of this condition occurring in a woman of thirty-seven, beginning during the seventh pregnancy. At the time the condition was very bad, and there was considerable complaint of pain in the pelvis. In the following seven years there were four pregnancies; and in the last the delivery was by version. At this time the patient was going about with the aid of crutches. Between the tenth and eleventh the patient fell, fracturing the thigh. When seen in the thirty-fourth week of the twelfth, the general condition was extremely bad. The right leg was two inches shorter than the left; the abdomen unusually prominent; there was a right kypho-scoliosis in the dorsal region, and left in the lumbar. The child was delivered by Cesarean section, the pelvis showing osteomalatic changes. After delivery the general condition was bad, and the patient was put to bed with the whole trunk placed on extension; and after eight weeks the condition was very much improved. The length of the body had increased seven inches. The right leg was nearly the same length as the left, and the patient soon was able to get about and attend to her household duties.

SUTURE OF TENDONS.

In the *Revue d'Orthopédie*, Dr. A. Dupureil reports a case of injury of the hand in which the deep and superficial tendons were cut, and in which operation was done later in the attempt at reunion. There was possible flexion of the phalanx on the metacarpus, probably due to the interossei, but none of one phalanx on the other. The operation was decided upon to attempt to rejoin the cut ends of the tendon. The incision was made over the site of the tendon of the index-finger; and in this, the distal end was found, but a long search failed to reveal the other end of the divided tendon. Therefore, the portion which was found was sutured to the tendon of the middle finger, and the wound closed. For a time there was no power of flexion over the finger, but this soon begun to appear, and later the use of the finger became almost as perfect as before the injury.

MALLET FINGER.⁴

Dr. Robert T. Mann reports two cases of this condition, which is described as being found after a blow on the end of the finger while extended, and in which some of the fibres of the extensor tendon are ruptured, resulting in a flexion of the terminal phalanx on the first and second. As a rule, the deformity is permanent, the tendon having little or no power over this phalanx. The treatment is by long incision over the site of the

injury, separating the tendon into the two natural fasciculi, and dividing the tendon transversely, advancing each point along its own side, and securing it to the skin at the base of the nail by a suture, tying on the outside. This is done rather than suturing through the periosteum, as it affords better hold. The nail is often lost temporarily; and after operation there is sometimes an over-extension, which disappears in time.

LAMINECTOMY FOR POTT'S PARAPLEGIA.⁵

Dr. Samuel Lloyd gives a comprehensive view of the condition of this subject at present, and the following deductions:

The operation is contra-indicated (1) in cases where there are other complicating tubercular lesions; (2) in cases where mechanical treatment has not been applied.

It is indicated (1) in cases where the posterior spinal disease is made out as the cause of the paraplegia; (2) in cases where the lesion seems to indicate the failure of mechanical treatment, that is, where dislocation has occurred or where a sequestrum is causing compression; (3) in cases where during the employment of intelligently applied apparatus the symptoms continue to increase in severity; (4) in cases where after a period of careful mechanical treatment, say eighteen months, the condition has remained stationary; (5) in cases where pressure myelitis threatens the integrity of the cord.

LATER RESULTS OF LAMINECTOMY FOR PARAPLEGIA DUE TO ANGULAR CURVATURE OF THE SPINE.⁶

Mr. W. Arbuthnot Lane gives the ultimate results of eleven cases previously reported by him. In two of the cases death occurred, but only one could be attributed to the operation; and of the other nine, two derived but temporary benefit. In the other seven the relief was permanent, both as regards the paraplegia and the local condition. He considers the operation one of not great severity, and one that should be attempted in all cases presenting these symptoms.

LATERAL DEFORMITY OF THE SPINE IN POTT'S DISEASE.⁷

Kirmisson reviews the literature of the past few years on this subject, and takes a neutral ground in reference to the etiology of this deformity. He describes the two forms which are met with: the one, in which the lateral deviation accompanies the angular deformity; and the other, in which the lateral deformity exists alone. The question of differential diagnosis is considered, but little new light is thrown on the subject. The presence of tenderness over the spinous or transverse processes is regarded as of value, existing only in the cases of caries. He calls attention to the fact that where the lateral deviation accompanies the kyphosis it may be either postural purely, or due to the bone change; but when existing alone, that it is due to muscular contraction. In the former, although under recumbency, the deformity may nearly or quite disappear, under suspension it is more marked by the increased muscular contraction. He considers the existence of the lateral deformity in Pott's disease as an indication for prolonged rest in bed.

Marlier⁸ adds a contribution to this subject, and re-

⁷ Revue d'Orthopédie, 1892, No. 6, p. 440.

⁸ Loc. cit., 1893, No. 3, p. 178.

ports a case in which there was a typical scoliotic curve in which there was pain in the side and leg, but the back showed no rigidity or muscular spasms, and also the child was able to walk about freely. A treatment of gymnastic exercises was given, but in the course of a few months a knuckle appeared and later an abscess. In this case there was not present the tenderness of pressure over the transverse process which is mentioned by Phocas, who reports a case with this symptom in a boy of fourteen.⁹ This case showed a slight projection at the point of deviation at the first lumbar vertebra. There were no subjective symptoms, and the motions of the back were entirely free. The case developed later with a kyphosis and abscess.

Dr. Ridlon¹⁰ gives cases in which this deformity is present, but in which the diagnosis was doubtful, and in which the lateral deformity was marked while the symptoms were light. He thinks the diagnosis should be based rather from the absence of muscular spasm than that of pain or of the character of the deformity, and that when the deformity is high when spasm is doubtful, the degree of rigidity should determine the diagnosis.

FORCIBLE CORRECTION OF ANGULAR DEFORMITY OF THE KNEE.

Dr. J. E. Goldthwait¹¹ reports altogether eleven cases which have been operated on within a period of from five years to one year ago. The contractions were from various causes, chiefly from tumor albus; a few from rheumatism, and one from gonorrhœa. In one the trouble appeared at the age of thirteen months and had existed until the time of operation, which was at the age of sixteen, at which time the leg was flexed at a right angle and markedly subluxated. At present the patient has a useful joint with free motion in an arc of ninety degrees.

In all of the cases the results were good, giving useful joints, crutches having been discarded. It is interesting to note that in all of the cases, the operation was followed by very little reaction or pain, and each case was up in two weeks.

For the employment of force in those operations the author had modified the apparatus devised several years ago by Dr. Bradford for the correction of the angular contractions of the knee, in which the deformity is maintained by fibrous adhesions. As modified, the apparatus is adjustable, and can be used upon any patient regardless of size. The arch on which the power is applied is movable on the uprights, and can be secured at any distance from the fulcrum. The counter-pressure comes upon a single leather pad, and is so placed that the force is always directed against the strongest part of the femur, no pressure coming along the epiphyseal line.

OPEN INCISION IN CONTRACTED KNEE.

Wahnean¹² reports from Schede's Clinic eight cases of open incision in contraction of the knee and hip, with healing by blood-clot. The same method is used successfully by Lorenz and Hoffa.

ETIOLOGY OF PES CALCANÆUS.

Bayer¹³ refers to the grouping by Nicholodani, in which all the cases of these were divided into two

groups, the congenital and the paralytic acquired, and reports two cases which he considers show that there should be added another classification to these two. In one there was a phlegmonous inflammation of the plantar region, and in the other an injury to the sole of the foot by a piece of broken glass. In both of these there was contraction resulting in this deformity of the foot. He considers that the condition is due to the position of the foot during walking, and that by the permanency of this the contraction occurs. In both of these cases the muscles of the calf were atrophied, and there was a secondary retraction of the muscles which resulted in the pathological condition of the foot.

(To be continued.)

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

HENRY M. JACKSON, M.D., SECRETARY.

REGULAR meeting, Wednesday, November 15, 1893, the President, Dr. F. C. SHATTUCK in the chair.

DR. H. F. VICKERY read a paper on

THE PREVENTION OF TUBERCULOSIS.¹

DR. V. Y. BOWDITCH: I am very glad to have the privilege of listening to Dr. Vickery's paper. I am sure it will bear good fruit. I think that no experiments that I have seen recorded thus far can compare in beauty of result with those of Dr. Trudeau made in 1886 or 1887,² in which he speaks of environment for the cure or prevention of tuberculosis. He made experiments upon rabbits and I should like briefly to review them. He took fifteen rabbits and divided them into three sets, five of which he inoculated with tubercular virus, and placed them in the best possible hygienic position, that is, putting them on an island in the middle of a lake and feeding them with vegetables every day. Another set he inoculated keeping them in a damp, dark place. The other five were not inoculated, but lived in a damp, dark place. After two or three months those on the island were caught and killed. In only one was there any symptoms of tubercular infection having been carried through the body, the others all being fat and remarkably healthy. In the five inoculated and put in the damp, dark place, four died in a few weeks and all were filled more or less with tubercular disease. The remaining one was tuberculous also. The others were simply kept in a damp, dark place without being injected with tubercular virus, and they were simply thin and miserable, but no tubercular disease was found upon examination after killing them a few months later. From this I think we can argue that among human beings environment can act in the same way. I hope very much that the Society will take some action upon this question. It seems to me that by combined effort we can accomplish very much more than by one man single-handed. I hope that some day we can see in Boston, as well as elsewhere, laws made by which no such buildings should be erected like certain apartment houses which I have

seen upon the Back Bay and in other places, where the only means of ventilation from the bed-room was by a door leading to the parlor or dining-room and one window opening into the well, three feet square, into which all the water-closets were ventilated. I wish also that we could do in Boston what they are doing in some places where in the public schools boys and girls are taught to avoid the disgusting habit of spitting in houses and in the streets. I wish also that the effort to stop smoking on the rear of the open cars had been successful, not for the smoking itself, but because of the filthy conditions of the back seats when ladies and others are obliged to get in them, for no one knows what sort of tubercular material may be there to be carried on their skirts. In regard to the action of boards of health in declaring tuberculosis an infectious disease in the same rank with diphtheria and small-pox and scarlet fever, I feel that we must be cautious. It is an infectious disease according to our present knowledge but not in the same degree as the others and the conditions are very different. It seems to me that with patients who are just beginning to show signs of pulmonary disease it would have a most depressing and deleterious effect to have such action taken as is now done for the acute infectious diseases. The greatest care, however, should be taken among the friends. They should be informed of the state of the patient and steps taken to prevent the spread of that disease as far as possible and within reasonable limits. I always direct my patients never to use handkerchiefs or any article of clothing, simply to have cloths or paper cups that can be burned immediately, or china sputa cups, the contents of which can be destroyed.

I think Dr. Vickery deserves the thanks of the Society for his paper.

DR. J. C. WHITE: From the title of this paper I hoped that some allusion might be made to tuberculosis of other parts of the body as well as of the lungs, because the communication of other forms from person to person as shown in skin clinics is no small evil. For example, I treated last year at the Massachusetts General Hospital thirty-five new cases of tuberculosis of the integument, in a condition to have extended the disease again in more serious forms possibly to other persons. For a long time, you know, the identity of lupus and other forms of tuberculosis was not recognized. Now it is known that a large proportion of patients with lupus eventually die of consumption. Such patients are generally members of families, and no means are taken to prevent contagion. We see many cases where, from the sputum undoubtedly, tuberculosis of the hands and lungs occurs in the same person. We observe the former especially in attendants upon consumptive patients and in those who have charge of children with scrofulous sores in the neck: scrofuloderma. Again, it is possible that a person with tuberculosis of the hands, or other forms of tuberculosis of the skin, may introduce the bacilli through the mouth to more dangerous tissues and thus produce more serious and rapidly fatal forms of the disease. I want to say also that I think it is a mistake to consider tuberculosis in any way on the same level of danger as scarlet fever and small-pox, so far as any attempt to control it by boards of health is concerned. It should be considered rather like leprosy, as it is communicated in the same way. Leprosy occurs still in some communities as frequently as consumption does in others, and if consumption were accompanied by such frightful ex-

ternal appearances and disfigurement as leprosy, no doubt the same methods of restraint might long ago have been used against it, and it might have been crushed out from civilized communities exactly as leprosy has been crushed out by exclusion, and although it would seem a cruel thing that we should treat patients with phthisis as lepers were formerly treated, there can be no doubt that if those measures were exercised, that we should exterminate tuberculosis from our midst. The lazarettoes in Europe several centuries ago were numbered by hundreds and it was only because such active means were taken that that disease was crushed out. I hope that this subject may be made the subject of more serious consideration on the part of this Society.

DR. E. O. OTIS: With very great interest in the general subject of pulmonary tuberculosis, Dr. Vickery's paper upon its prevention has especially appealed to me and I feel indebted to him for its presentation. I am, as he is, a member of the Pennsylvania Society for the Prevention of Tuberculosis, and I wish we had some similar society in this community. It seems well nigh an hopeless undertaking to prevent contagion when you consider the innumerable ways and avenues by which the disease may be disseminated. Consider how constantly we are exposed to the contagion almost everywhere we go—in the various vehicles which transport us—steam and street cars, carriages; in the various buildings we enter, halls, hotels, theatres. How many thousand people are constantly expectorating bacilli in-doors and out. The physician himself—so familiar is he with the disease I suppose—in so many instances does not seem to realize the danger of contagion or the importance of guarding against it in every possible way. Consider the waiting-rooms in our out-patient departments where there is generally a not inconsiderable number of tuberculous patients, waiting anywhere from a half-hour to an hour and a half and who expectorate about to their own and the risk of others. Then consider the matter of vocation: poor people are obliged to keep at their work so long as they are possibly able to do so, and so we have many tubercular cases working with others and exposing them constantly to the dangers of the disease; for example, I had last winter at the dispensary a *baker* with quite advanced pulmonary tuberculosis; often he was unable to work, being without means he slept every night in a bake-house through the kindness of one of his friends; what an opportunity for the dissemination of the contagion. It seems to me one of the great needs of the present day are hospitals, State, City or National for the care and seclusion of poor tuberculous patients. As it is now, no adequate provision is made for them in any of the charitable institutions and they wander about often ending their lives in the poor-house.

One other point I wish to refer to, and that is the matter of proper respiration. I have had the opportunity of examining a good many so-called well people in regard to this and it seems to me that we do not give sufficient consideration to it. We must *teach* people to breathe properly. We must remember that the city life is for the most part a sedentary one, and unless we give especial attention to it we rarely fully inflate our lungs. It has got to be a matter of conscious exertion. Each day, and several times a day, I believe, full lung inflation should be practised. It is one of my standing rules, in advising men as to exercise in

the gymnasium, that they should take deep full breaths several times a day. After this is practised a while they establish a custom of breathing more deeply and fully all the time.

DR. GREENLEAF: I regret that I was unable to hear Dr. Vickery's paper. The subject is one in which we are all especially interested. While we may no doubt accomplish much towards the prevention of tuberculosis through the efforts of boards of health and by other general measures, there is a way of preventing its spread, which we may carry out as individuals. The idea for this was suggested to me largely through the investigations of Dr. Stone, who found that the dried sputa of consumptives contained living bacilli after a considerable length of time. I think his observations showed that the bacilli were alive and capable of causing tuberculosis in animals after at least three years. Such facts show the very great necessity for having some means of disinfecting the sputa as soon as passed. In hospitals we have the sputa cups, but they do not meet the difficulty we find with patients when outside, whether in the streets, the cars, the hotels or in their own homes. It occurred to me that if we could have something in a convenient shape and of such material that patients would use it whenever they expectorate that we should accomplish a good part of the battle, and these samples which I take pleasure in presenting to the Society this evening demonstrate one way of meeting the problem. My first thought was to have a small bit of thin paper of paraffine or other impervious material and place on it a small wad of absorbent cotton, then to have the patient use one every time he expectorated, roll it up and put it in his pocket or a convenient receptacle and then burn all the wads immediately on reaching home. I advised such for a while. An improvement on this plan appeared to be to have the bit on which each sputum was to be passed made of absorbent material only, and then to wad these up and store them in a bag of impervious material, and then burn bag and all on reaching home. I am endeavoring to have a manufacturer make up such napkins for me by the wholesale, so that they will be as inexpensive as possible and yet sufficiently neat in appearance so that patients of every condition may be induced to use them. In the meantime I am advising my patients to buy the form of absorbent cotton, known as lintine, which comes in a convenient thickness, or sometimes thick enough for two or three napkins. I have them cut the rolls into small squares, say three by three inches as in these samples, then I have them use simple brown paper bags to put them in.

I have used these especially in the Boston Dispensary and have found no difficulty in getting the patients to adopt them on explaining to them the possibility that they may have taken their disease by having inhaled particles of dried sputa carelessly or ignorantly expectorated by other consumptives in places where they have slept or have otherwise been exposed; moreover I carefully explain to them that unless they adopt some such device they are likely to similarly infect their relatives and friends.

I would add that I do not confine the use of these napkins to consumptives. I endeavor to encourage their use in every disease accompanied by expectoration, partly with the idea of making it a little easier for the consumptives, so that they may be relieved of the possible odium of being the only users of such napkins,

and partly to be especially on the safe side regarding all forms of the offensive and dangerous habit of expectoration.

DR. O. K. NEWELL: I am very glad to have heard this interesting paper. I think that I have sent fully a half-dozen cases to Professor White's clinic recently where there has not been any doubt at all that there was a direct auto-infection producing tuberculous disease in children who were living in families where there was consumption. Dr. Otis says there are a great many sources of infection, but I think the two real sources of evil are in the first place the sputa, especially in this country where we are reputed to be a nation of expectorators, and in the next place the overcrowding. I think that Dr. Vickery's statement that as far as overcrowding is concerned the same conditions were to be found in Philadelphia as here is incorrect. In Philadelphia the question of overcrowding is practically eliminated because it does not exist. There are square miles of small houses and it is a well-known fact that in that city there are more single homes than in any other city in the world; there being 60,000 to 70,000 more buildings in Philadelphia than in New York City. Although they may not have perfect drainage in Philadelphia, there is not overcrowding. In reference to the advisability of boards of health taking the same attitude towards tuberculosis as towards scarlet fever, etc., I think that the fairest way to consider that subject is to remember that scarlet fever and diphtheria and such diseases are rare diseases comparatively. They are acute and rapid in their course and rapidly dangerous, whereas tuberculosis is an extremely common disease, one that is only inoculable with difficulty. The seriousness of the disease depends upon where the inoculation is made. If dried sputum is inhaled into the lungs it is in a place where it is impossible to get at it. If the eye is inoculated of course it is easy to reach it. I think that tuberculosis of the skin is not very dangerous; it is only when it involves the lungs that it is such a serious danger.

DR. E. O. OTIS: I neglected to mention a case which came to my attention a few days ago, and was of interest to me on account of the possible source of infection. It was this: A young man apparently well had been shooting, and while returning fell with his gun, wounding his thumb; he had on a pair of woollen gloves at the time, which he continued to wear after the wound was received. He went directly from Norfolk, where the wound was inflicted, to Washington and there visited the Army Medical Museum. The wound did not heal kindly, the finger was amputated, but still healing did not ensue and local tuberculosis was discovered at the seat of the wound. Later he developed pulmonary tuberculosis for which he is now at a health resort. Was it from the woollen gloves or at the Medical Museum that the bacilli gained entrance into the wound? It is an interesting conjecture.

DR. WHITE: I should like to mention the fact that I once counted the number of sputa in crossing the Common from Park Square to the West Street gate. It was early in the morning after two or three trains had come in on the Providence railroad. The temperature was below freezing. I was attracted by the great number of fresh sputa on the sidewalk and counted many hundreds before I got to the West Street gate. Very likely many of them came from persons with consumption. They were safe at the

moment because frozen, but the same number of sputa on that path in the summer would rapidly dry and be taken up by the wind and pass into the atmosphere. So, I think, we are in the constant presence of bacilli in the air from sources which are not apparent. I was going to the hospital a few days ago and passed a house in which a woman was engaged in shaking rugs out of the window. A few weeks previously the red card of scarlet fever was on that house. Very likely those rugs had been in the chamber with the patient. Children passing might readily have taken the disease.

DR. F. C. SHATTUCK: I was very glad to hear Dr. Vickery speak of the soil. I think that in the ardor of our enthusiasm at having discovered the cause of tuberculosis, as is very natural, we have at first been inclined to attribute too little importance to the question of soil; and those experiments of Dr. Trudeau, which Dr. Bowditch quoted, are certainly very important and should not be lost sight of for a moment. It is not a very easy matter to determine the relative importance of contagion and susceptibility. Within a fortnight I have seen two ladies with pulmonary tuberculosis following the death of sisters from pulmonary consumption, — ladies who had nothing to do with each other whatever, in two entirely different families. There you may say there was family predisposition. The sisters who survive were about those who were ill a good deal of the time, and it has been noted before that cases of contagion from husband to wife are more frequent than from wife to husband, the women naturally staying in the house a great deal more. But I recall a case of another kind. Some years ago I was asked to take charge of a kept woman who had pulmonary consumption and afterwards developed tubercular disease of the bladder. The young man who kept her behaved in a way different from some men, and stuck to her through thick and thin, and as far as his means would allow provided her with everything which would contribute to her comfort. He continued to go to see her. She died; and not long afterwards he came to my office feverish and with a sharp stitch in the side. I found that he had pleurisy, and sent him home to another city in the State. He pretty rapidly developed consumption, and some years later died at Saranac. He probably got his trouble from his mistress, and not through coitus. Then we have on the other side the statistics of the Brompton Hospital for Consumptives in London; the very small number of cases which have developed among attendants or physicians. And the physicians to out-patients sit three or four hours in small consulting-rooms in the most intimate contact with consumptive patients. So very common, so omnipresent we may say, is the contagion of tuberculosis that it seems almost a wonder that any of us survive. I am perfectly convinced, although it is very difficult to prove that many people are tuberculous and never know it; have pulmonary tuberculosis and get well of it. If one-seventh of all deaths from all causes at all ages are due to consumption of the lungs, I should like to know how large a contingent of the population is tuberculous somewhere or other and does not die of it. I do not dwell upon this with a view of discouraging any attempt to limit the spread of the disease which undoubtedly occurs through the sputum. It is only that I think we are apt to look too strongly on one side, and the side which presents itself to us now is the side of contagion naturally springing from the discovery of that in which the contagion resides.

DR. VICKERY: I should like to express my satisfaction in having the opportunity of hearing the opinions of other members of the Society and to say that that was one of the objects which I had in mind in writing the paper. What Dr. Otis said about respiration is confirmed by such writers on climate as Solly. As to the effect of notification in shocking early cases: I have thought of that too, and it is a valid objection, but still I find that after a while it seems wiser to me for my patients to know what they have, although perhaps if they were told the first day it might do them a great deal of harm. I have in mind some to whom the knowledge has come very gradually, but still while they have been in the early stages, and without any apparent detriment; and I have been told by a patient lately that at Saranac Lake they know what they have got and it is intended they should, so that they will take the best care of themselves. There are two sides to the matter. I think there is no doubt that the disease is contagious. I remember one case that struck me very much; a perfectly healthy mother of middle age had a married daughter come home to die of consumption. She nursed her with great assiduity and buried her. In about a year after I was called to her to see her die in the same way. It seemed to me a very plain case. Of course, we have all met similar ones. If I am going to be poisoned and killed by a disease it is not much comfort to me to know that it may not happen next week, that it is going to hang over me and kill me gradually. About cases of unconscious tuberculosis, there have been interesting pathological reports in that regard, and a good many cases are found in adults who present healed scars and who die of other diseases.

DR. BOWDITCH: I wish to emphasize one thing I said. It is in reference to cases of tuberculosis being reported to boards of health. Now while I agree with Dr. Vickery that sooner or later it is usually best that a patient should know that he has tuberculosis (I refer now to the pulmonary form) yet I maintain that for many reasons in some cases it may be wisest not to let him know at the outset, although the family or friends should know the true facts. If then, we were to follow the same rules as apply to scarlet fever, diphtheria, etc., and under the penalty of a fine for neglect, were compelled to notify the board of health the instant we detect the disease what would be the result? I need not picture the disastrous results to the patient were such active steps taken. I do not yet know the exact course the Michigan State Board of Health takes in this matter, but I must confess to having been startled by their announcement that they class tuberculosis with the acute infectious diseases, a position which I think now unjustifiable. With caution and with rational methods I believe an immense deal of good can be done by boards of health in this matter, but let us keep within bounds.

DR. NEWELL: It seems to me the boards of health can cover these two points and they do to-day practically in what relates to overcrowding. They could educate the people in regard to spitting and regulate the overcrowding without taking the same action that they do towards cases of acute contagion.

DR. VICKERY: I remember that Flick suggests that cases should be reported when the tissue begins to break down. I think that would be very difficult to carry out. I am sure many cases would not be reported. Perhaps if we started by enlightening the

public, after a time they would thank us to know it. I would thank any man, if I had beginning tuberculosis, to let me know it right away. That is from my point of view, and I think that the public may be brought to the same position.

DR. J. J. MINOT: I move that such a committee be appointed by the Chair as Dr. Vickery suggests in his paper, the committee to make a report on the best means of preventing the development of tuberculosis. Seconded. Carried.

The PRESIDENT: I will announce the committee at the next meeting.

THE NEW YORK NEUROLOGICAL SOCIETY.

STATED Meeting, held at the New York Academy of Medicine Tuesday evening, November 7, 1893, DR. B. SACHS in the chair.

DR. EDWARD D. FISHER read a paper on

ANOMALOUS CASES OF GENERAL PARESIS.

He stated that a general definition of general paresis may be given as a disease of the nervous system, especially of the brain, in which, pathologically, we find a diffuse inflammation of the membranes and cortex of the brain, and also of the membrane and systemic tracts of the cord. Typical cases follow a more or less well-defined course, the somatic and psychical symptoms going on hand-in-hand, and finally terminating in two or three years in death. Of late years many cases have been reported which differ largely from the ordinary clinical picture. Savage refers to a type of case in which all the physical signs of the disease are present, but none of the mental or psychical, or, again, when only dementia of a simple character is present. He found that the course of the disease may often in these cases be protracted, extending over many years. Dr. Fisher said it is not an infrequent experience to have our diagnosis disputed, both by the friends and by the physician in attendance, in this form of the disease, especially as under proper care improvement takes place, and because the disease is so long protracted. There may in the future be subdivisions made of the general disease as the symptomatology and pathology are better understood. It has suggested itself to him that when either alcohol or syphilis seems to be a prominent exciting or etiological factor the so-called somatic symptoms are usually the most marked. Another explanation of these cases may be that the prodromal stage is protracted. In fact, the disease, as a rule, long antedates its first recognition by friends and physician. In mental diseases, the emotions are probably the first to show evidence of change. This may express itself by undue exhilaration over a slight thing in itself, by depression, by outbursts of irritability, by a disregard for the feelings of others, etc.; or the patient may become careless, or show a lack of proper concern in regard to his health or business. On the somatic side we may have evidence of slight motor disturbance, perhaps slight tremor, slowness or clumsiness in speech, or a slightly ataxic or spastic gait. In other cases, again, the early symptoms may indicate hypochondriasis, only later on to develop with rapid strides into a well-defined case of general paresis.

Dr. Fisher then gave the histories of a few cases of general paresis coming under his observation which pursued an anomalous course. In the first case the

disease extended over a period of at least nine years, and in all probability much longer. The second case was that of a man aged thirty-eight years; excepting that he is rather forgetful and has lost interest in his personal affairs to a large extent, no mental symptoms are present. The man has the peculiar fatuous expression common to the disease; there is some tremor of the tongue and slight tremor of the face; speech clumsy; he has had two or three attacks of aphasia of short duration, lasting from several hours to a day. At times there appears to be great improvement in his condition. This will probably prove to be one of the prolonged type of cases. The man is still under observation.

Dr. Fisher said that considering these cases and many others to which he could refer, in which the course of the disease seems to be almost arrested, or even does not commence in the usual manner, it must be seen that general paresis, at least in some cases, may be much altered in its course—to such an extent, indeed, as to make the diagnosis a question of doubt. Some dementia, however, he thought always exists in these cases. Even in the early stages of a classical case, with exaggerated ideas of wealth and ability, we recognize the inconsequence of ideas and responsibility so essentially characteristic of dementia. This latter condition becomes more apparent if these cases are allowed to engage in their ordinary avocations. It will often be seen that when they are removed from hospital care, and permitted to resume their business when improvement takes place physically and mentally, that the course of the disease becomes a rapid one towards physical exhaustion and dementia.

DISCUSSION ON THE RELATION OF SYPHILIS TO GENERAL PARESIS.

DR. FREDERICK PETERSON opened the discussion by reading a paper on this subject. He stated that the question of the position taken by syphilis in the etiology of dementia paralytica is one that has been attracting great attention among syphilologists and alienists of late years. No fewer than seventy authors have contributed to the elucidation of this problem. The majority of these contributions treat of the subject from a statistical standpoint, and it would seem that sufficient data have been collected to fully satisfy all inquiries regarding that particular. Naturally, the first point upon which precise information was needed was as to the percentage of cases of general paralysis with a history of syphilis, and we are now in a position to supply it fully. Although these statistics differ very materially at times, yet the results in the main agree. The figures range from as low as 13 per cent. to as high as 88 per cent. Kjellberg has taken the stand that all cases of general paralysis are of syphilitic origin; that the cases are affected either congenitally or through acquisition. This author stands quite alone in his assertion, which is not justified by observation or facts.

Dr. Peterson said his own statistics on this point are rather questionable, as are all obtained from large public asylums to which patients are taken in stages of the disease too far advanced for them to give trustworthy information regarding themselves, and whether they are generally brought by relatives or officers unacquainted with such an etiological factor in their histories. There were admitted to the Hudson River State Hospital for the Insane 287 cases of general

paresis. In 55 of these syphilis was definitely ascertained to have preceded the disorder. In the remaining 232 it was either absent or unascertainable. Actually, then, only 19 per cent. were found to be syphilitic; but, assuming that one-half the others were affected, the total ratio would be in the neighborhood of 60 per cent. of the cases. At public dispensaries we see these cases in the earliest stages, when histories may be more exactly obtained. At the Vanderbilt Clinic, 40 cases of general paresis were observed; definitely syphilitic, 10; definitely not syphilitic, 12; unascertained, 18; taking the 22 cases in which the exact facts were obtained, we have 45.4 per cent. certainly syphilitic, and 54.5 certainly not syphilitic. From an examination of all the figures collected above from various sources, it would, perhaps, be fair to assume that about 60 to 70 per cent. of all cases of general paralysis have a syphilitic history. The fact is thus established that syphilis is a striking etiological factor in general paresis, but that 30 to 40 per cent. of the cases are not syphilitic. A much more difficult problem is to determine the exact relationship between syphilis and general paresis. Is it a direct cause, or merely a contributing agent? Is it in syphilitic cases a post-syphilitic affection, or is foregone syphilis merely a predisposing factor? This problem may be examined from several standpoints. In the first place, we have the rather remarkable statistics of Lewin, of 20,000 cases of syphilis, one per cent. of which became insane, and in which not a single case of general paresis developed. Then we have the further fact that among the native Egyptians, where syphilis is one of the most widespread of disorders, no case of general paresis has as yet been reported. It is significant, by the way, that alcoholism is seldom or never observed among them. Again, from the pathological standpoint, it is well known that the direct invasion of the brain by syphilis is characterized by changes in the blood-vessels, by the formation of gummata, or by diffuse meningeal infiltration. The first and third of these processes is most frequent in and about the base of the brain; the second is more common in cortical regions. On the other hand, in general paresis we have a chronic meningitis of the convexity, with atrophy of the cortex, and the processes in this disease and in syphilis are quite distinct, although there are cases in which a syphilitic meningo-encephalitis may closely simulate, symptomatically, dementia paralytica.

There are some who argue that tabes and general paresis are frequently associated, and that tabes being a form of syphilitic disease, general paresis in consequence must owe its origin to syphilis. If the two diseases have the same etiological imprint, there ought to be a close correspondence in the percentages of syphilis in relation to each; but the consensus of opinion seems to be that a history of syphilis is found in only 60 to 70 per cent. of general paresis, whereas in tabes the percentage ranges, according to different authorities, from 80 to 98 per cent. At the Vanderbilt Clinic, in 83 cases of locomotor ataxia, 51 were syphilitic, 20 not syphilitic and 12 unascertained. Of the 71 cases of tabes of whose specific history we have exact data, over 71 per cent. were syphilitic and over 28 per cent. not syphilitic. That is, then, among cases equally well studied and from the same sources, 45.4 per cent. of general paralytics were syphilitic, and 71 per cent. of tabetics. Dr. Peterson said he did not agree with the statement made by Dr. Sachs in a re-

cent article, that there is a very frequent development of tabes after dementia paralytica, and of dementia paralytica after tabes. In cases of paralytic dementia with tabetic symptoms the nerve fibres of the posterior columns are often little if at all implicated. One of the facts which has been employed against the opinion that general paresis is a late form of specific disease is the absolute futility of anti-syphilitic treatment. In every form of cerebral syphilis proper we are often enabled to accomplish a great deal of good by vigorous and systematic treatment, whereas in general paresis, even if the history of syphilis is clear, no appreciable effect is produced by anti-syphilitic remedies.

In concluding his paper, Dr. Peterson said that in his opinion dementia paralytica has no immediate or late relations to syphilis as a direct cause. Syphilis is a common etiological factor, but only in the sense of its being a predisposing cause. It prepares the soil in more than half of the cases for the development of dementia paralytica, this disorder having its direct causes in alcoholism, sexual excesses and over-strain of the mental functions. The higher nervous elements are rendered prone to degeneration by the fore-running specific disease, which, as is well-known, gives rise to a cachexia with changes in the constitution of the blood.

DR. GRANGER said that the question of a change in the character of the mental symptoms of paresis from the standard type of the disease is one that has been very much debated and studied; and it looks as though the outcome of it might be that the disease known as general paralysis of the insane would be found to embrace more than one disease — possibly more than two — the distinction being based upon the clinical aspect and the pathological conditions present. The variations from the ordinary type of the disease, as he has observed them, have not been so marked in this country as abroad. Two or three per cent. would probably cover the melancholic form of paresis in this country; while in England, in some of the largest asylums, the number has risen as high as 15 or 20 per cent. of the cases admitted. He has seen two forms of the melancholic type of paresis: in one of these the delusions of the patient, although they were those of depression in one sense, were of grand depression. For instance, a patient was very much depressed with the idea that he was the devil; he would constantly cover his face and head in order to hide his horns, and carry a newspaper behind him in order to prevent his tail from growing. But he was the biggest devil, the greatest and the wickedest devil that could be imagined. On the other hand, there are cases of general paresis in which there is simply melancholia with no grand delusions. Another anomalous type of paresis is that in which no special symptoms are present, excepting that of progressive dementia and a feeling of satisfaction; this type is becoming more and more common. The question whether the disease is lengthening or shortening in its course is very much discussed; many think that its course is being shortened, while on the other hand, according to some of the English asylum reports, it is being lengthened. In this country we still commonly see the typical form of general paresis, and death takes place about thirty months after the full development of the disease.

In regard to the relation of syphilis to general paresis, Dr. Granger said he agreed very closely with the views expressed by Dr. Peterson. Syphilis itself

does not cause the disease, and it is very difficult to tell what does cause it. That syphilis is very common in Egypt, and that venereal excess is also very common there is acknowledged by all, and that general paresis is very uncommon there is also true, but other conditions exist there which the world over are favorable to the non-development of paresis. These natives possess neither energy nor ambition, and spend most of their time basking in the sun. In the coal regions in England, general paresis is quite common, the percentage in the asylums being from 30 to 40 per cent.; in the adjoining agricultural districts the percentage falls as low as two or three per cent., and yet probably syphilis and intemperance are very common in both of these communities. In this country, general paresis rises as high as 15 to 20 per cent. in the Eastern States, while in the Western and Southwestern States the percentage is very low indeed. Yet syphilis is undoubtedly very common in the latter localities; so is drunkenness; still, general paresis is very infrequent there. It takes something besides syphilis or intemperance to produce the disease. In the cities we call it the strain due to high civilization. In the coal regions we call it their laborious and peculiar life. Syphilis, while it does not cause paresis, is undoubtedly a strong factor in its production. As regards the value of statistics in this connection, the speaker thought it extremely difficult to get accurate statements from the patients who are sent to asylums, and upon these we are usually dependent for our statistics. The history of syphilis often dates back many years and is extremely untrustworthy.

DR. LYON said he has often been struck by the fact that when a history of syphilis is obtained in a case of general paresis, the former disease usually existed a long time ago. Most of the patients state that they were treated for the disease and cured, and that they have had no manifestation of it for many years. During the current year seventeen cases of general paresis were admitted into the Bloomingdale Asylum; of these, twelve have a pretty clear history of syphilis. In only one of these was the syphilis as recent as four years previous to the development of the general paresis. In almost all the cases the patients had probably received the modern treatment for syphilis, that is, mercury and the iodides.

Dr. Lyon said he agreed with the previous speakers, that while syphilis is not the immediate cause of general paresis, it is one of its provoking causes; it produces instability of the brain, which then yields to other more immediate causes. These same patients who give a history of syphilis have for many years led liberal lives. The course of the paresis in these cases seems to be more rapid than in those uncomplicated by syphilis. The speaker said that cases of paresis of long duration are not unknown—indeed, not very infrequent. He has met with one case in which the disease lasted over ten years. Its duration depends on the patient's constitution.

Dr. FIELD referred to the unreliability of statistics obtained from patients affected with general paresis. He has never seen a paretic in whom active syphilitic symptoms existed. The history of syphilis obtained is usually an old one. It is generally combined with a history of alcoholic and venereal excesses. He has made inquiries among those engaged in the treatment of venereal diseases, and who have followed up their syphilitic patients for many years; and they have in-

formed him that general paresis is not common among such patients, although it does occur. Dr. Field said he regarded syphilis as a predisposing rather than a precipitating cause of general paresis. This is also true of alcohol. Maguin says that chronic alcoholism always terminates in dementia or general paresis. The Chinese are well known to be syphilitic—at least, those in this country; still, he has only observed one case of paresis among them. That case was a typical one: the patient imagined he had thousands of acres of land, thousands of dollars and thousands of wives—all white. The reports of the asylums in California show many cases of insanity among the Chinamen, but no form of paresis. In conclusion, Dr. Field referred to the change of type that seems to be occurring in dementia paralytica.

DR. JOSEPH COLLINS inquired on what grounds Dr. Fisher based the statement that in general paresis due to alcoholism or syphilis the somatic symptoms were supposed to be in the ascendancy over the mental? If such a statement be well founded, it is in contradiction to the other diseases due to these poisons, wherein mental symptoms are well marked. At the Medical Congress in Washington some years ago, Dr. Savage referred to a variety of paresis wherein the motor and somatic symptoms were apparently the only symptoms of the disease for quite a long time. Such a case, Dr. Collins said, is now under his observation. As regards the statement made by Dr. Peterson that cases of paresis are unknown in Egypt, Otto has recently reported fifteen cases of the disease in that country. So far as the relationship between syphilis and general paresis is concerned, Dr. Collins said he was very much in accord with the statements made by Dr. Peterson. His statistics correspond very closely with those of Jacobson, taken from the St. Hans Asylum in Denmark; and it appeared to him that such statistics could be relied upon. The patients in that institution came from within the narrow confines of the State; and Jacobson, in making up the statistics, ferreted out every possible etiological factor by inquiry regarding the patient's antecedents, friends, etc. The statement made by the French syphilographers, and also by Sternberg, of St. Hans Asylum, that there can be no general paresis without a history of syphilis is no longer worthy of credence. We have statistics galore at our command, and it is now time to draw such conclusions as can be drawn from figures. Dr. Peterson's statistics, taken from the Vanderbilt Clinic, are very valuable. The cases were seen early; they were apparently carefully studied, and are sufficient in number to draw conclusions from. We all admit that in about 60 per cent. of all cases of general paresis a history of syphilis, dating back from one to twenty years can be obtained. What we want to know is the way in which syphilis causes general paresis. In one of the specimens presented by Dr. Van Gieson this evening, a section taken from the brain of a general paretic, the microscope shows a large number of cells collected around a blood-vessel, with some of their protoplasmic prolongations destroyed or atrophied. In the early stages of general paresis there is vaso-motor disturbance, not only in the cortex of the brain, but throughout the whole body. Syphilis may act through its sinister manifestations on the blood-vessels. It causes a pathological condition that is favorable to the development of general paresis. If there are other attributing factors—and in nearly all cases there are—they

act as the torch to the pile that has already been prepared.

DR. PARSONS, in referring to the possible relationship between syphilis and general paresis, stated that so far as his observation and reading went, the tissue changes that occur in general paresis do not correspond with those that are produced by syphilis. Furthermore, we know that general paresis occurs in a certain number of cases in which there is no history of syphilis. His own studies of dementia paralytica have led him to think that the more immediate causes of the disease depend upon emotional conditions, or one might say congestion of the capillaries of the cortex due to over-exertion or over-stimulation of the nerve cells of the cortex. Syphilis sometimes causes a degeneration of the nerve tissue, but in opposition to this we observe that general paresis occurs usually during the most vigorous period of life. Dr. Parsons said that while he felt unwilling to make the statement that there is no possible relationship between syphilis and paresis, as cause and effect, such causative relation has not yet been proven.

DR. WILLIAM M. LESZYNSKY said that in those patients who have died from general paresis, it seemed to him that the pathological changes found in the brain were very much the same in those who gave a history of syphilis, and those in whom a specific history could be positively excluded. Dr. Hinckley, of the Essex County Asylum, at Newark, N. J., recently sent him some statistics in connection with this subject. The asylum has about 500 inmates. During the past eight or ten years, 15 cases of general paresis were received there. Of these, 13 were males, two females. In only two of these cases was a history of syphilis obtained, and in those there were no somatic manifestations of the disease. The causes given in the remaining 13 cases were alcoholism, overwork, anxiety, etc. In conclusion, Dr. Leszynsky said he agreed with Dr. Peterson in considering syphilis only as a predisposing factor in the production of general paresis.

DR. A. D. ROCKWELL referred to certain cases of general paresis that have come under his observation, in which the patients for temporary periods were extremely wretched, utterly disregarding all rules of tidiness and decency; these manifestations, after a number of weeks, passed away, and the patients became quite reasonable again.

DR. C. H. BROWN said he regarded general paresis as a disease of evolution; syphilis, alcoholism, sexual excesses, etc., were merely complications or predisposing factors. He also referred to the difficulty of getting a reliable history of syphilis in these cases.

DR. E. D. FISHER, in reply to Dr. Collins's question as to the ascendancy of the somatic over the mental symptoms in certain cases of general paresis, said he referred to those cases where we have extreme alcoholism or a recent history of syphilis. In such cases, too, we frequently have a more rapid response to treatment; however, they do not, as a rule, go on to complete recovery. While the old typical cases of general paresis are still the ones usually met with, yet anomalous cases are not infrequent. These, perhaps, in the past would not have been classed as general paresis. He agreed with Dr. Peterson in regarding syphilis simply as a predisposing factor. In cerebral syphilis we may have many symptoms similar to those of general paresis, but the disease does not run a similar course. Asylum reports on this subject must always

be regarded with more or less suspicion. In conclusion, Dr. Fisher referred to the futility of specific treatment in dementia paralytica.

DR. J. F. TERRIBERRY referred to the difficulty of properly classifying certain cases in which there is dementia and other symptoms of cortical degeneration.

DR. SACHS said that too much reliance should not be placed upon the value of statistics in connection with this subject. A few years ago the number of cases of tabes with a syphilitic history was placed at 87 per cent., and much lower than this by some authorities; now every one is agreed that the figures should have been as high as 92 per cent. We all admit the frequency of syphilis in general paresis, but the majority of the speakers have laid too little stress upon it as a predisposing cause; they refer to it as the lesser cause. The speaker said he did not agree with them in this. In other mental diseases in which heredity plays an important part, that factor is regarded as a predisposing cause, while an emotional element is regarded as the exciting cause, but the hereditary taint is certainly one hundred fold more important than the latter element. He is of the opinion that syphilis plays a more important rôle in general paresis than any other etiological factor. Other facts go to prove that syphilis plays a very important part in dementia paralytica. In probably every case of general paresis that has occurred in early life, that is, between the ages of fifteen and twenty-five years, there is a history of syphilis. The general impression seems to be that the specific history is one of long standing. While this is true in the majority of cases, it is not so always. A striking instance of this recently came under his observation. A young man of 22, while a student at Heidelberg, contracted syphilis: six months after infection he developed a typical general paresis, from which he is still suffering.

As regards the possible relationship between tabes and general paresis, Dr. Sachs said he has seen a number of cases in which the development of the two diseases rapidly followed each other. In one case the tabes developed nine months previous to the general paresis; in that case there was an undoubted history of syphilis. In one class of parietic patients the kneejerks are much exaggerated, while in another they are below the normal or entirely absent. In these latter cases the probability is that changes in the posterior columns have occurred closely related to the changes that are found there in posterior spinal sclerosis.

DR. PETERSON then closed the discussion. As regards the statement made by Dr. Collins about the cases of general paresis found in Egypt, Dr. Peterson said he has not seen the article by Otto referred to. Dr. Sandworth, the physician in charge of the asylum at Cairo, informed him that he had never seen a case of general paresis in a native Egyptian, nor had his predecessor, who was there for many years. The disease does occur among the Turkish officials in Egypt, but not among the natives.

With regard to Dr. Sachs's statement as to the relationship between tabes and general paresis, it is of course true that there are often tabetic symptoms in general paresis, and that the kneejerks may be absent. In the majority of cases, however, in which the kneejerks are absent in the early stage of the disease, they subsequently return and become exaggerated. Furthermore, no changes are found in the posterior columns after death from general paresis.

Recent Literature.

Reform in the Treatment of the Insane — Early History of the Retreat, York: Its Object and Influence, With a Report of the Celebrations of its Centenary. By D. HACK TUKE, M.D., LL.D. Pp. 96. London: J. and A. Churchill.

The volume before us contains an interesting but short account of the rise and growth of the now famous York Retreat and the work done there by several generations of the Tukes, from the pen of one of their number, himself an eminent alienist and writer on insanity and kindred subjects. The achievements of Samuel Tuke in England and Pinel in France form an epoch in history; and the reforms in the care and treatment of the insane by them instituted will rank with the highest efforts for the alleviation of human suffering. This small volume commemorative of the centennial of the York Retreat, may therefore properly stand as a fitting memorial of the inception of a great work for the amelioration of the insane, and thereby the good of mankind.

Psychopathia Sexualis, with especial reference to Contrary Sexual Instinct: A Medico-Legal Study. By DR. R. VON KRAFFT-EBING. Authorized translation by CHARLES G. CRADDOCK, M.D. Pp. 436. Philadelphia and London. 1893.

The alienist is often in much doubt regarding the status of certain distasteful cases which come to his notice in whom the sexual element is the chief, perhaps the only, feature. It is here that this work will be a decided help, for in it not only are the unmistakable cases of contrary sexual instinct given a practical classification, based upon an apparently sound pathology, but other less pronounced manifestations and syndromes of similar nature, generally held to be simply the expression of vice in its most revolting form, are here taken from their criminal setting and placed in the proper category of mental degeneration. At the same time the boundary line between sexual depravity and disease is kept well defined.

In the matter of treatment there is little advice given that is of practical value. The cases in which the author tried hypnotism do not seem to have been particularly successful, and his encouragement of marriage for such patients strikes us as reckless in the extreme and not warranted by the results.

It is unfortunate that such a book should be needed, albeit it is a masterly production and one that is thoroughly scientific in tone and method; for its circulation cannot, of course, be confined to medical readers. On the contrary, by translation the seven editions of the original are likely to be speedily duplicated and given a greater notoriety, owing to the pornographic interest on the part of the public.

Hypnotism, Mesmerism and the New Witchcraft. By ERNEST HART, formerly Surgeon to West London Hospital, etc. Pp. 182. New York: D. Appleton & Co. 1893.

The publication in book form of the papers on this subject by Mr. Hart which have appeared recently in the *British Medical Journal* and the *Nineteenth Century* is most welcome. They will do a good service in making easy of access a remarkably clear, concise and forcible exposition of much of the folly and humbug

connected with hypnotism, mesmerism, "animal magnetism," objects of psychical research, and "the occult" generally; although the author, in his impatience with credulity and imposture, is often unnecessarily severe in his strictures, and at times far too sweeping in his statements. It is refreshing to read such a fearless attack upon the hypnotic craze of to-day — we had almost said, yesterday. The subjection of research into psychical phenomena of all sorts to rigid control tests is not only here insisted upon, but has been practised also by the author to some purpose, notably in his exposure at great pains of the theatrical "hypnotic" performances in the wards of Dr. Luys at the Hôpital de la Charité. The "psychological researchers" are also not spared, and telepathy is shown to have "no more substantial foundation than mesmeric trance or clairvoyance, although the name sounds better to modern ears." The abuse and evil effects of hypnotism are graphically and convincingly set forth, and his estimate of its therapeutic value placed none too high. In fact, the limit he puts to its use is somewhat too restricted, but the author's experience and the extent of the folly will explain and excuse all.

Anatomy, Descriptive and Surgical. By HENRY GRAY, F.R.S. A new American, from the thirteenth English edition. Edited by T. PICKERING PICK, Surgeon to St. George Hospital, etc. Philadelphia: Lea Brothers & Co. 1893.

This new edition is a decided improvement over all preceding ones. Gray's Anatomy has always been a favorite with students, and deservedly so, though precise anatomists have at times found a good deal to criticise. It has held itself rather aloof from modern methods of instruction of Continental origin. It has been very English. A change has been manifest in recent editions. The present one shows it more than ever. The book has become more comprehensive, but without the sacrifice of its characteristic merits. Of late American editions have had as an appendix Holden's "Laudmarks," edited by Dr. Keen. This is now done away with. Its place is more than taken by the sections on surface form and on surgical anatomy scattered throughout the book. Many new and excellent illustrations have been added. T. D.

The Diseases of the Male Organs of Generation. By W. H. A. JACOBSON, M.Ch., Oxon., F.R.C.S. Philadelphia: P. Blakiston, Son & Co. 1893.

In this work the author maintains the deservedly high place which he has won in medical literature.

The volume covers satisfactorily and thoroughly the ground indicated by its title — with the exception of some conditions of the prostate — to which shortcoming the writer himself draws attention in his preface.

The subject is divided into five parts, which treat respectively of the diseases of the testicle, of the cord, of the scrotum, of the vesicular seminales and of the penis.

In the first division, that part which relates to misplacements of the testis and the complications in connection therewith, presents in a concise and interesting manner, much useful knowledge of a kind hitherto not readily accessible.

Chapter VI (of Part I), which relates to tubercular disease of the testis and its appendages, is perhaps the most important contribution this volume contains. In it the author discusses the theories regarding the

channels by which infection of the epididymis and testis occurs; also the vexed question as to whether the disease is primary in these organs or secondary to tuberculosis in some other portion of the genito-urinary tract — his conclusion, with which we are in accord, being, that the epididymis is the most frequent primary seat of the disease. He also considers that the bacilli are carried principally by the blood-vessels, and in a less degree through the lymph-channels.

A short *résumé* is given of the evidence with respect to the occurrence of tuberculous infection by means of sexual contact.

The rare manifestation of the disease in the form of "galloping testicular tuberculosis" is well described.

In regard to the surgical treatment of the disease in these organs, the author strongly advocates incision — thorough curetting and antiseptic cleansing of all tubercular swellings of epididymis and testis — at any rate, and leans toward the side of the more radical operations by early excision of the affected parts, while recognizing that this is still an open question.

While writing of "Atonic Impotence," the author indorses the view of Professor Gross, to the effect that urethral stricture is a frequent result of masturbation. In this conclusion we do not concur, never having been able to satisfy ourselves of its truth during a long period of careful investigation with reference to this point.

We are unable to give a more extended account of the many excellent and valuable matters to be found in this book, but must be content to add, in concluding this notice, a word of praise for the admirable manner in which the work is illustrated as well as written, and to the fair-minded way in which the author has set forth the various theories bearing upon the more important parts of the subjects presented, while at the same time he has avoided that error into which the judicial mind sometimes falls, namely, that of lack of perspection, or of proportion with relation to their importance, of the matters presented.

The publishers have produced the book in a convenient size. The type is excellent, as are the other details for which they are responsible.

The work has the useful quality of not being beyond the reach of under-graduate students, while, at the same time, it meets the needs of the practising physician, and we take pleasure in cordially recommending it to the attention of both.

The Recrudescence of Leprosy, and its Causation. A popular treatise. By WM. TEBB. London, 1893.

In this book of 412 pages, the writer, a well-known lay opponent of the practice of vaccination, attempts to show that the spread of leprosy is owing to a great and unrecognized degree, to compulsory arm-to-arm vaccination as a preventive of small-pox. It is simply an amplification, after much travel and considerable study, of a previous brochure on the same subject that has already been noticed in these columns. Mr. Tebb has visited the West Indies, British Guiana, Venezuela, Norway, California, the Sandwich Islands, Ceylon, Egypt, New Zealand, Cape Colony and Natal; together with most of the colonies in Australia; and his book is mainly composed of quotations from journals and medical writings, together with an account of some conversations with superintendents of asylums and other people whom he met in his travels. The mass of evidence and cases collected is very large, and, if carefully sifted, may prove of value to the student

of this disease; but it cannot be said that the writer has gone very far towards proving his case. It is not for an instant to be doubted that both syphilis and leprosy have been inoculated by vaccination, and that the greatest care should always be taken to avoid impurity of lymph; but that this procedure is in great measure responsible for the existence of leprosy no sufficient proof is given. Many of the cases cited in favor of this view are loosely reported, and are utterly inadmissible as evidence on either side. Some few of the cases point to vaccination as a probable cause. The mass of statistics and material is introduced without order or critical comment, and little attempt is made to discriminate between skilled and ignorant observers. The book bears the mark of one little versed in scientific research, and is colored throughout by the writer's obstinate antagonism to one of the greatest boons ever conferred upon humanity. The writer's honesty and zeal, however, are certainly to be respected, and the amount of time spent in travelling in search of information must have been very great. The book will not have been written in vain if it causes a greater degree of caution to be taken in communities (as the Sandwich Islands, for instance) where it seems probable that careless and improper vaccination has been the source of disseminating disease; but the attainment of the writer's aim, namely, the utter suppression of vaccination and the abolition of all attempts at experimental therapeutics in leprosy, can only be regarded in the light of a great calamity.

An Introduction to the Study of Diseases of the Skin.

By P. H. PYE-SMITH, M.D., F.R.S. Philadelphia: Lea Brothers. 1893.

This book has been compiled from the chapters on diseases of the skin which were written in 1886 to complete the late Dr. Hilton Fagge's work on medicine, together with several papers that have appeared in "Guy's Hospital Reports" and the "Pathological or Clinical Transactions." The author has had abundant opportunities for observing skin diseases, having been in charge of the department for cutaneous diseases in Guy's Hospital for a series of years, and has "tried to make his description an epitome of what he has himself observed." The book is interesting, as setting forth the views and experience of a leading London practitioner who has devoted considerable time to the study of dermatology.

The Medical Student's Manual of Chemistry. By R.

A. WITTHAUS, A.M., M.D., Professor of Chemistry and Physics in the University of the City of New York, etc. Fourth edition. New York: William Wood & Co. 1893.

A book which is so favorably known as this one is does not need extended comment. In the present edition no important changes have been made in that part of the work which is devoted to inorganic chemistry. The part treating of the chemistry of the carbon compounds has been extended by about twenty pages, and the text in great part rewritten. The organic compounds are classified, as in previous editions, according to their constitution so far as is known, and those alkalis whose molecular structure has been completely or partially determined, occupy in the present edition their proper places in the classification. We consider the book one of the best text-books on chemistry for students of medicine.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JANUARY 4, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

VACCINATION AND REVACCINATION.

THE rarity of small-pox in Massachusetts during the past dozen years or more has been such that scarcely one in ten of the physicians now in active practice has ever seen a case of the disease. Hence the difficulty of diagnosis which very frequently happens when cases do occur, or when other diseases simulating small-pox are met with in the practice of young physicians who have entered upon the duties of their profession since the epidemic of 1872-73. There is no reason to suppose that the remarkable immunity which our population has had the good fortune to enjoy for several years will be indefinitely prolonged, since an unvaccinated population, consisting both of immigrants and of unvaccinated infants born since the last epidemic, is likely to furnish the combustible material for a future epidemic, whenever the disease gains a foothold among us.

Fortunately, we have a sure preventive, in vaccination and revaccination, when thoroughly and properly performed under the supervision of an intelligent physician or sanitary officer. With abundant resources in the shape of plentiful supplies of lymph, obtained by calf-vaccination, there can be no excuse on the part of local sanitary authorities for neglecting this important preventive measure.

The present outbreak is by no means confined to Boston. Emigrant ships arriving at United States sea-ports have brought small-pox to this country many times during 1893, from crowded cities where this disease is almost constantly occurring in Europe. Outbreaks have occurred in many Western cities during the year; and with the present facilities of intercourse by rail and by steamer, the spread of small-pox is rendered much more certain than it was in earlier times. A recent summary of the deaths from small-pox in Massachusetts during the past twenty years, shows that, out of the 161 towns in which these deaths occurred (mostly in 1872-73) only eight were not directly on some line of railway communication at the time when the death occurred.

During the year just closed, there have been 678 cases of small-pox in the city of Reading, Pa., a city having scarcely one-eighth as many inhabitants as Boston.

While it is true that single cases are liable to occur anywhere, as in the case of unvaccinated immigrants, it is also true that extensive and widespread outbreaks following such first cases, can only occur in places where the preventive measures of vaccination, notification, isolation and disinfection are neglected.

The importance of revaccination is also apt to be underestimated; but the history of those countries where revaccination has been thoroughly enforced places the value of this measure beyond a doubt. An illustration of the value of revaccination is shown in the case of Germany since the law of 1874 went into operation. By the provisions of this law every infant must be vaccinated, and in addition every scholar in public and in private schools must be revaccinated at the age of twelve years. The provisions of this law have been so thoroughly carried out that, as a consequence, Germany has enjoyed an immunity from small-pox far exceeding that of any of the contiguous countries, particularly Austria, Russia and France.

In support of this statement the following figures are presented from Dr. Sykes's "Public Health Problems," London:

MORTALITY FROM SMALL-POX PER 100,000 LIVING.

	Pruss'n Army.	Austri'n Army.	Austria.	Prussia.	Berlin.	London.	Vienna.
1870	33.32	17.28	35.18	17.52	22.37	30.20	44.71
1871	27.67	40.1	30.30	213.21	632.56	242.16	71.90
1872	5.65	101.4	189.99	262.37	132.61	53.46	536.98
1873	2.68	106.0	223.36	33.65	11.21	3.55	224.50
1874	0.33	67.0	176.18	9.52	2.47	1.66	136.26
Revaccination compulsory.							
1875	0.0	21.5	57.73	3.60	5.19	1.32	113.50
1876	0.0	10.4	39.28	3.44	1.81	20.80	187.49
1877	0.0	25.5	16.91	0.34	0.40	70.98	84.01
1878	0.0	15.4	5.57	0.71	0.78	38.41	75.91
1879	0.0	22.7	50.88	1.26	0.75	12.18	46.91
1880	0.0		81.27	2.60	0.81	12.50	73.52
1881	0.0		78.10	3.82	4.74	61.91	122.95
1882	0.0			3.64	0.13	11.07	104.29
1883	0.0			4.00	0.33	3.00	9.6

These figures show that Prussia, although exposed to constant danger from small-pox, upon its Russian and Austrian borders, has been enabled to reduce its small-pox mortality to exceedingly low terms by means of vaccination and revaccination; and the Prussian army, which constitutes a very large portion of the population, has, with the exception of a single death in 1885, been absolutely exempt from deaths from small-pox.

The effects of vaccination and revaccination upon the attack-rate, and the death-rate from small-pox, during an epidemic in a large city, are well illustrated by the admirable report of Dr. Barry upon the epidemic of 1887-88 in the city of Sheffield, England. The following were the attack- and death-rates per 1,000 of the population at each of the two age periods, children under ten years and persons over ten years of age:

	Unvaccinated.	Once Vaccinated.	Twice Vaccinated.	
Under ten,	101	5.	0	} Attack-Rate.
Over ten,	94	19.	3.	
Under ten,	44	0.09	0	} Death-Rate.
Over ten,	51	1.	0.08	

These figures may be summarized as follows: "The children vaccinated had, as compared with the unvaccinated, a 20-fold immunity from attack, and a 480-fold security against death from small-pox; the persons over ten years of age, once vaccinated, had a 5-fold immunity against attack, and a 51-fold security against death; and the twice vaccinated, a 31-fold immunity from attack, and a 640-fold security against death."

In commenting further upon the significance of these figures, which are the result of a most careful house-to-house canvass in a city of about 200,000 inhabitants, Dr. Sykes says:

"We may conclude, therefore, that natural insusceptibility to small-pox practically does not exist, that the contagion is so far-reaching, so readily attacks indiscriminately the unprotected, and is so fatal, that in a community, *entirely* unprotected, either by previous small-pox, inoculation or vaccination, an epidemic causes an enormous mortality; that the disease leaves the survivors disfigured, maimed or weakly, but protected more or less against future attacks, so that the disease continues to fall only upon the unprotected, namely, the newly born and infant population, the few survivors of which remain protected for a number of years.

"Vaccination protects the infant and the young population in proportion to the number vaccinated, and the quality and quantity of the vaccination marks; but the protective influence of vaccination fades sooner than that of an attack of the disease, so that in later years susceptibility to small-pox returns. Revaccination compensates for the less duration of immunity, and practically brings artificial immunity to a protective level equal to a previous attack of the disease, so that periodical revaccination almost entirely averts small-pox."

The first law in Massachusetts in regard to small-pox was enacted in 1809, and provided for the inoculation of the inhabitants with the cow-pox, under the direction of the town boards of health, or of a committee chosen for the purpose. The present law provides that parents and guardians shall cause their children and wards to be vaccinated before they attain the age of two years, and revaccinated whenever the town authorities shall, after five years from the last vaccination, require it. The town authorities shall also require and enforce the vaccination and revaccination of all inhabitants when the public health requires it. The penalty for neglecting to comply with these provisions is five dollars. Towns shall furnish means for vaccination to those who cannot pay for it. Incorporated manufacturing companies, and superintendents of public institutions, are required to see that the inmates of such institutions are vaccinated. Towns may make further provisions for vaccination, under the direction

of the board of health or of a committee chosen for the purpose. School committees are required to exclude unvaccinated children from the public schools.

Practically much of this law is a dead letter. The last clause is the most efficient part of the law. As a matter of fact, there is to-day a large unprotected population in Massachusetts, made up partly of unvaccinated immigrants and partly of unvaccinated native-born Americans. The same conditions obtain probably to a greater extent in other States.

The degree of protection afforded by a primary and secondary vaccination may be estimated in some measure by the size and character of the scars. It is impossible to formulate a positive rule as to the period of protection acquired by any given individual. Revaccination, if properly done upon a subject neither very old nor very feeble, is a small penalty to pay for immunity. If it does not take, the individual has the assurance of probable immunity and no harm is done; if it does take, there is at once the evidence of its necessity and the assurance of reacquired safety. Although there is now no epidemic of small-pox in any part of New England, the present conditions are such and so widespread as to indicate to thoughtful and intelligent people the desirability of vaccination and revaccination.

NAIL BITING.

A FRENCH scientist and surgeon, Berillon, has just issued a brochure on "Finger-Nail Biting" (*onychophagie*), containing the results of a series of observations in the public and private schools of France and extending through a period of more than seven years.

His observations lead him to pronounce the habit far more widespread and pernicious than would be imagined, and force him to conclude that, if not a disease itself, it is an unfailing mark of incipient degeneration of the nervous system, which, if unrecognized, may be productive of the most evil results.

In a mixed school of the Department of l'Yonne, the report showed the following results:

	Number Examined.	Nail Biters.
Twelve to fourteen years, . . .	13	7
Thirteen to fifteen years, . . .	16	6
Fifteen to seventeen years, . . .	18	3

From twelve to fourteen seems from this to be the age most susceptible to the habit. A like experiment with girls shows them to be even more susceptible at this age.

	Number Examined.	Nail Biters.
Ten to thirteen years, . . .	80	27
Twelve to fifteen years, . . .	75	21
Fifteen to sixteen years, . . .	52	13
Sixteen to seventeen years, . . .	10	2

In all the schools where the children have been the objects of careful and attentive observation, the reports have agreed in pronouncing that pupils observed to have the habit are universally the poorest students; that if boys, they are inclined to effeminacy, and if girls, to slackness. In many, there are marked defects of character and less sustained attention.

Berillon's careful inquiries elicit the fact that nail biting is not to be looked at merely as a child's habit, unpleasant and punishable, but as a direct and positive indication of hereditary physical degeneration. So marked is this, that he has found no families in which nail biting has been observed to be general whose head has not been either an alcoholic, an unbridled gambler, a convulsive, a feeble-minded person, a lunatic, a criminal or a consumptive.

In such families the hereditary degeneration is to be observed, unhappily, in more than nail biting. Often the heads of such children present species of deformation, such as microcephalus, bony crests and protuberances on different parts of the head, while the face reveals crossed eyes, near-sightedness, irregular teeth or displacement of the features. At this point, reversing the inquiry, Berillon gave his attention to a large class of nervous patients in the Paris hospitals and found that a considerable proportion of the children of these show the habit of nail biting, with other signs of physical degeneration.

Berillon thinks his experiments prove that nail biting as a habit in children has its source deeper than mere imitation or childish idiosyncrasy. He regards it as no wilful habit to be cured by ordinary petty punishment, but an indication of an incipient degeneration of the nervous system, which, once observed, may be treated understandingly at its very beginning. The outward habit, if it does not disappear when the cause is removed, will yield to ordinary treatment.

While M. Berillon's statistics are interesting, we do not feel that such unhappy conclusions are wholly warranted from his cases. School-children, especially girls, eat chalk and slate-pencils, and pass at a certain age through a condition which might be called "philopickle-lime-phagia"; and we think that a child may bite its nails without danger of passing to a state of idiocy. On the other hand, we can recall some nail biters who had been blessed with very intelligent and estimable progenitors.

CONTAGIOUS DISEASES IN PUBLIC SCHOOLS.

DR. MOREAU MORRIS has made a report to the Board of Health of the City of New York in regard to the spread of diphtheria and other contagious diseases among the children in the public schools. He found that it was the custom in all the schools that he visited for the scholars to use slates and pencils in common, these articles being kept in baskets from which they help themselves indiscriminately. The habit children have of putting their pencils in their mouths and of cleaning their slates with saliva is well-known, and the reporter suggests, as has been before suggested, that disease is frequently conveyed by this agency. It is therefore recommended that the use of slates be discontinued altogether, that all books which have been used by sick children should be destroyed, and that school-books should be covered with hard paper instead of muslin, as is now done, on account of the liability of the latter to retain disease germs.

MEDICAL NOTES.

A PHYSICIAN IN THE ITALIAN CABINET.—Dr. Baccelli, Professor of Clinical Medicine at the University in Rome, and President of the Royal Academy of Medicine, has been made Minister of Public Instruction in the new Italian Cabinet.

DEATH AT AN ADVANCED AGE.—James Morris, a negro, died at Lyons, N. Y., last week at the age of one hundred and twenty-one years. He was born in slavery in Delaware, and his age was authenticated by the family records. It is not stated whether he ever saw George Washington.

A VINDICATION OF DARWINISM.—A man was recently arrested in Central Park, New York, for assaulting a monkey in one of the cages because it made up faces at him.

AN OPPORTUNITY FOR A PHYSICIAN.—The *Medical News* prints the following advertisement, which appeared in the *Philadelphia Press* of December 11, 1893, "as another illustration of the mercantile demands for and uses of physicians":

WANTED.—A Physician to travel with medicine company to lecture; experience not necessary: prefer one who can play organ; a steady, pleasant and lucrative position offered. Address, etc.

THE IOWA BOARD OF MEDICAL EXAMINERS.—This board has ordered that on and after July 4, 1898, no medical school shall be considered as of "good standing," for the purposes of registration of its alumni within the State, unless it has a four-course curriculum. Each course of attendance upon medical lectures must be not less than six months long, but two courses in the same year will not be counted for two full courses.

A PEASANT'S IDEA OF THE CHOLERA.—Two Russian peasants in Tomsk were recently sentenced to imprisonment for the murder of a woman whom they had "taken for the cholera." A quarantine had been established in their town against the cholera in the neighborhood. On the morning of the murder the peasant woman had come to town, but was turned back at the outpost. Soon afterwards the two men left the village; and in a short time gunshots were heard near by. One of the men on trial said later in the day to his neighbors: "Pray to God. We have killed the cholera: It is dressed like a woman above the waist and like a man below." The men were convicted, and sent to jail for three years.

MEDICAL MARTYRS.—Commenting on the deaths of medical men from diphtheria recently recorded in the *British Medical Journal*, the *St. Petersburg medicinische Wochenschrift* says such occurrences are by no means rare in Russia. Within the last few weeks two practitioners of Sengilei in the Simbirsk Government, M.M. Radsiminski and Chrenow, have died of diphtheria contracted from patients under their care. Two young Parisian physicians have died this autumn from diphtheria taken from a patient.

LOOKING AFTER BARBERS AND HAIRDRESSERS.—The Government of the Republic of Colombia in

view of the possibility of contagious diseases, such as ringworm, favus and syphilis, being transmitted by combs, brushes, etc., has passed an enactment making it compulsory for all barbers and hairdressers to keep the instruments of their art clean, and to disinfect them every time they have been used.

BOSTON AND NEW ENGLAND.

SMALL-POX IN BOSTON.—Only one new case of small-pox has occurred the last week. The patient is a man living in the same tenement-house in which the first group of cases occurred at the South End. There are now fifteen patients in the hospital.

A NEW EMERGENCY HOSPITAL IN BOSTON.—A new Emergency Hospital, to cost about a hundred thousand dollars, is to be built by the friends and trustees of Tufts College; and the clinical advantages are to be given wholly and exclusively to the students of the Tufts Medical School.

ILLEGAL USE OF PHARMACY CERTIFICATES.—The first cases under the new law of last June by which the State Board of Registration has power to suspend any person's registration as a pharmacist, and his certificate, for such term as may be deemed fitting, and in flagrant cases to revoke the certificate, occurred last week. All three holders were charged with letting out their certificates to unqualified persons. The charges were proven, and one certificate was revoked and the other two suspended.

REPORT OF THE CHILDREN'S HOSPITAL.—The report of the managers of the Children's Hospital in Boston for the year 1893 says: "The year, just closed, has been an unusually busy one in all the departments and the results have been most successful and satisfactory. At the beginning of the year there were in the wards 41 patients; treated during the year, 295 boys and 287 girls. In addition, 2,071 new cases have been cared for in the out-patient department. Most of the patients admitted to the wards have been free patients." The Board of Officers elected is the same as last year with the exception of Mr. Oliver Ames 2d, who succeeds to his father's place.

THE SCHOOL FOR THE BLIND.—The sixty-second annual report of the trustees of the Perkins Institute and Massachusetts School for the Blind shows that there are now 287 blind persons connected with the establishment. The financial record shows a balance of \$8,248.

FREE VACCINATION IN BOSTON.—The appropriation of \$5,000 for free vaccination has been exhausted; but the Mayor, in view of the satisfactory working of the public inoculation, has authorized the continuance of the work, and has told the Board of Health that the money expended will be granted when the work is completed. The number of persons vaccinated increased each day last week from 1,000 on the first Monday to over 4,000 on Saturday, a total of over 20,000 for the week.

SMALL-POX PRECAUTIONS IN CAMBRIDGE.—The Board of Health of Cambridge has opened public stations for free vaccination, and has secured from the City Council the sum of \$5,000 with which to build a hospital for contagious diseases. During the cholera scare a year ago the Board petitioned the City Council for \$4,500 for this purpose, but the appropriation was not given.

INFLUENZA AT SEA.—One of the steamers from Boston to New York reports that on her last voyage she was signalled from the Vineyard Sound Lightship, that most of the crew were sick with the grip, and in need of medical attendance. A steamer was sent from New Bedford with a physician.

NEW YORK.

INFLUENZA.—On December 18th it was reported that there were more than five hundred cases of grip at Dunkirk, N. Y., and three deaths had occurred.

SOFT COAL.—For some time past complaints have been made of the increasing use of soft coal by various manufacturing establishments in the city, by reason of which the atmosphere is contaminated by bituminous smoke; and the Board of Health has now issued peremptory orders that the nuisance shall be abated.

A BULLET IN THE SKULL FOR SIXTEEN MONTHS.—A case of unusual interest has recently occurred at St. Luke's Hospital. On November 21st a male patient, thirty-one years of age, was admitted suffering from severe spinal trouble, who stated that fifteen months before he had shot himself in the back of the neck with a pistol. On December 20th he died, and the bullet was found imbedded in the base of the skull. The cause of death was found to be pressure on the spinal-cord from vertebral dislocation, together with spinal meningitis, which were produced by the ball, which had remained in the body for sixteen months.

A LION ON AN OPERATING-TABLE.—At the New York College of Veterinary Surgeons, on December 29th, the operation of setting and dressing the fractured femur of a lion from one of the down-town museums was successfully accomplished. The lion was kept quiet by a hypodermic injection of morphine.

DEATH FROM A SPIDER'S BITE.—While engaged in helping to put up the Christmas decorations in the Episcopal Church at Sparkhill, on the Hudson, a young woman was bitten on the cheek by a spider which had been brought in on the greens, and in a few days death resulted from septicæmia.

APPOINTMENTS TO THE STATE BOARD OF HEALTH.—Governor Flower has appointed as members of the State Board of Health Dr. John Edwards, of Gloversville, to succeed Dr. Dawes, of Saugerties, and Dr. Murray M. Adams, of Watertown, in the place of Professor Perkins.

MORTALITY.—During the week ending December 23d, the number of deaths reported in the city was 818, which is an increase of 43 over the mortality of

the previous week, and 11 above the average for the corresponding weeks of the past five years, and which represents an annual death-rate of 22.19 per thousand of the estimated population. During the week there were 166 deaths from pneumonia, an increase of 33, and six deaths from influenza, against three during the week ending December 16th. During the week ending December 30th the number of deaths from influenza increased to 14, but the deaths from pneumonia showed a decrease of 22. The total number of deaths for the week was 824, which is 21 less than the average of the corresponding weeks during the past five years. This represents an annual death-rate of 22.34, against 22.91 for the same week since 1886. There were 637 cases and 88 deaths reported from contagious diseases, against 599 cases and 78 deaths in the week ending December 23d.

THE VITAL STATISTICS FOR 1893.—During the year 1883 there were reported 51,516 births, 16,144 marriages and 44,370 deaths in the city. In 1892 the figures were, respectively, 49,447, 16,001 and 44,329. The death-rate for 1893, estimated on a population of 1,827,396, was 23.46, which is the smallest ever recorded; the lowest previous death-rate having been 23.65, in the year 1877. The number of deaths from some of the principal diseases in 1893 were as follows: influenza, 220 (495 in 1892); small-pox, 100; measles, 387; scarlet fever, 531; diphtheria, 1,962; whooping-cough, 340; typhoid fever, 380; typhus fever, 201; diarrhoeal diseases, 3,314; cardiac disease, 2,376; bronchitis, 1,569; pneumonia, 6,476 (635 more than in 1892); consumption, 5,101 (5,033 in 1892); sun-stroke, 43 (against 320 in 1892).

APPROPRIATION FOR CHARITIES AND CORRECTION.—For the year 1894, the Board of Estimate and Apportionment has allowed \$2,295,675 and \$425,080 for the expenses of the Departments of Charities and Correction. For 1893, the appropriations were, respectively, \$2,223,425 and \$470,239.

HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.—As December 30th and 31st were both snowy days, it is to be feared that the annual collection of the Hospital Saturday and Sunday Association will prove smaller than usual this year. In its appeal to the public for liberal contributions for the hospitals the Association states that it has been found that, through the obliteration of old methods of individual competition by the establishment of large corporations and trusts in modern times, the income of rich charitable institutions as are supported by the individual gifts of the benevolent has been seriously affected.

REPORT OF THE STATE BOARD OF HEALTH.—The bulletin of the State Board of Health for the month of November, issued December 30th, shows that the reported mortality has further decreased from the low daily average of 290 in October to one of 281, which is the same as that of November, 1892. This is uniformly the healthiest month in the State of New York, the number of deaths per day being less during

November by 25 than the daily average for the past eight years. Compared with November, 1892, the zymotic mortality, and also the infant mortality, is lower; both are also lower than during the month of October. Typhoid fever caused the same number of deaths as in November, 1892, and 75 fewer deaths than in October. Scarlet fever continues, with little change, to be less prevalent than last year. There is an increase in measles since October, chiefly in New York City. Diphtheria caused about the same number of deaths as in last November. The death-rate for the month from all causes is 15.35, against 15.83 in October.

Miscellany.

THE CHANGES IN THE PHARMACOPŒIA.

THE new pharmacopœia of 1890 became official this week. For the convenience of our readers we give a list of the new remedies which are now official as well as of those which are no longer recognized. Certain changes in official nomenclature are important for correct usage in the future. There are eighty-eight new articles, and ninety have been omitted.

The newly-adopted articles are the following:

Acetanilidum, acidum hypophosphorosum dilutum, acidum stearicum, adeps lanæ hydrosus, alcohol absolutum, alcohol deodoratum, aloë barbadensis, aloinum, aqua aurantii florum (diluted), aqua chloroformi, aqua hydrogenii dioxidi, aqua rosæ (diluted), aspidosperma, barii dioxidum, caffeina citrata, caffeina citrata effervescens, calcii sulphas exsiccatus, cinnamomum saigonum, cocainæ hydrochloras, convallaria, elastica, elixir aromaticum, elixir phosphori, eriodictyon, eucalyptol, extractum apocyni fluidum, extractum asclepiadis fluidum, extractum aspidospermatis fluidum, extractum cimicifugæ, extractum convallariæ fluidum, extractum eriodictyli fluidum, extractum jalapæ, extractum lappæ fluidum, extractum menispermii fluidum, extractum phytolacæ fluidum, extractum rhamni purshianæ fluidum, extractum scoparii fluidum, extractum uvæ ursi, extractum viburni opuli fluidum, ferri et quiniæ citras solubilis, glyceritum acidi carbolici, glyceritum acidi tannici, glyceritum boroglycerini, glyceritum hydrastis, hydrastinæ hydrochloras, hyoscine hydrobromas, hyoscyaminæ hydrobromas, lithii citras effervescens, menthol, methyl salicylas, naphthalinum, naphthol, oleatum zinci, oleum betulæ volatile, oleum cadinum, oleum terebinthinæ rectificatum, pancreatinum, paraldehydum, pepsinum, petrolatum liquidum, petrolatum spissum, physostigminæ sulphas, pilulæ catharticæ vegetabiles, pilulæ ferri carbonatis, potassii citras effervescens, pryogallol, resorcinum, rhamnus purshiana, salol, sodii nitris, sparteinæ sulphas, spiritus amygdalæ amaræ, spiritus aurantii compositus, spiritus glonoini, spiritus phosphori, strontii bromidum, strontii iodidum, strontii lactas, strophanthus, suppositoria glycerini, terebenum, terpini hydras, tinctura lactucarii, tinctura quillajæ, tinctura strophanthi, trochisci santonini, viburnum opulus, zea.

The articles dismissed are:

Abstractum aconiti, abstractum belladonnæ, abstractum conii, abstractum digitalis, abstractum hyoscyami, abstractum ignatiæ, abstractum jalapæ, abstractum nucis vomicæ, abstractum podophylli, abstractum senegæ, abstractum valerianæ, acetum lobeliæ, acetum sanguinaris, æther, ammonii phosphas, ammonii sulphas, amylium iodatum, aurantii flores, azederach, cannabis Americana, ceratum extracti cantharidis, ceratum sabine, charta cantharidis, chinoidinum, chloroformum venale, chinecona flava, cornus, cupri acetas, cydonium, elixir aurantii, emplastrum ammoniaci, emplastrum asafoetide, emplastrum galbani, emplastrum picis canadensis, extractum cornus fluidum, extractum lactucarii fluidum, extractum mali, extractum mezerel, fel bovis inspissatum, ferri oxalas, galbanum, gaultheria, gutta-percha, hydrargyri sulphidum rubrum, ignatia, infusum brayeræ, juniperus, lavandula, linimentum cantharidis, linimentum plumbi subacetatis, liquor ferri et quiniæ citratis, liquor gutta-perchæ, liquor pepsini, magnesii sulphas, magnolia, maltum, mistura magnesæ et asafoetide, mistura potassii citratis, mucilago cydonii, oleum lavandulæ, oleum ruta, oleum succini, oleum valerianæ, origanum, pilulæ ferri

compositæ, pillulæ galbani compositæ, pix canadensis, potassii sulphis, potassii tartaras, prinos, rosmarinus, salix, sodii bicarbonas venalis, sodii santoninas, spiritus odoratus, syrupus ferri bromidi, syrupus limonis, thuja, tinctura conii, tinctura ferri acetatis, tinctura ignatiæ, trochisci magnesie, trochisci sodii santoninatis, unguentum acidi gallici, unguentum mezerel, unguentum sulphuris alkalinum, ustilago, vinum album fortias, vinum aloes, vinum aromaticum, vinum rhei, viola tricolor.

The figures are taken from the records of the Edinburgh Dispensary from July, 1886, to December, 1891.

"Insusceptibility."—No case occurred in which an infant was found insusceptible to vaccination by the arm-to-arm method. **Repetitions.**—Sixty-one cases required the vaccination to be repeated, owing to want of success on the first occasion. **Erysipelas.**—Seven cases of this dangerous accident occurred, and in almost every case the dwelling-house of the family was found to be damp or otherwise unhealthy. **Suppuration of Lymphatic Glands.**—This complication of vaccination also occurred seven times out of 5,866 cases. **Syphilis.**—There was no case of syphilitic infection. **Deaths.**—Two deaths resulted from the complications of vaccination—one from erysipelas, the other from blood poisoning following the suppuration of a lymphatic gland in the axilla. Both deaths took place about three weeks after the operation. **Revaccinations.**—Only 45 revaccinations were performed. The large proportion of these were on boys between the ages of twelve and fourteen, employed at the General Post-office. Among the laboring classes few came to the dispensary to be revaccinated, and these only when compelled by their employers. It would be much to the advantage of the community were revaccination made compulsory."

BLOOD PRESSURE IN DIPHTHERIA.

THE appalling rapidity with which death may follow the first clinical evidence of heart paralysis in diphtheria has led Friedemann¹ to experiment upon a series of cases to determine whether sphygmomanometric measuring of the blood pressure could give the physician an earlier warning of the cardiac poisoning, especially in children. Sixty-three cases were studied, in all the measurements were taken upon the radial artery and when the child was in a recumbent position and, if possible, during sleep. His results were as follows: The most favorable prognosis was for such cases as showed at no time any variation in the pressure, more than the slight rise and fall which was noted in nearly every case, and which, when not over five or ten millimetres of mercury, was of no moment. The second class of cases, which, though they ended in recovery after a longer or shorter time, gave the physician much anxiety, were those in which there was a continued fall of pressure. So long as the manometer did not fall below seventy-five to ninety millimetres of mercury (according to the age and size of the child), the prognosis was still fair. A lower pressure than seventy-five millimetres was considered serious and a pressure of less than sixty-five was almost invariably cause for a fatal prognosis. Twenty-six cases at one time or another showed an abnormally low pressure, seventy millimetres or less, Hg. Fifteen of these showed a sudden dangerous fall within the first week, and of these fifteen only two recovered, death in the other cases occurring within seven days. In the remaining twelve cases which first showed a fall of blood pressure after the first week of illness, five recovered and seven died within eight days afterwards. The general result of the observations was that a regularly-recorded measure of the blood pressure gave the earliest warning of approaching danger, which often was not shown by clinical signs until later.

¹ Jahrbuch. f. Kinderheilkunde, xxxvi, p. 50; Centralblatt f. med. Wissenschaften, 1893, p. 48.

SOME VACCINATION STATISTICS.

THE present outbreak of small-pox in Boston would undoubtedly cause but little alarm were it not for the fact that the complete freedom from the disease for the last twenty years has resulted in a widespread carelessness regarding vaccination. Nearly a whole generation has grown up since the last epidemic, and a surprisingly large number of these young people have not been vaccinated. The increase in foreign immigration has been large, and comparatively few of this class of people seek vaccination under less stimulus than fear.

Some statistics of vaccination of 5,866 cases recently published by Mr. Francis Cadell in the Edinburgh *Medical Journal* are of especial interest at this time.

Correspondence.

"SENDING PATIENTS AWAY FROM HOME."

1517. STOUT ST., DENVER, COL.,
December 27, 1893.

MR. EDITOR:—In connection with Dr. Knight's paper in a recent issue (December 21, 1893), I wish to call attention once more to a matter which needs to be mentioned frequently. I refer to a habit that some physicians, no doubt actuated by a mistaken kindness to the patient, have of stating to the patient about starting for Colorado, that he had "a little trouble in his bronchial tubes," or "a little chronic bronchitis," or merely "that he is a little run down." Many such patients come here, and we all see them occasionally, with the idea that other persons who come are consumptive, but that in their own cases there is nothing of serious import. Hence they are likely to rebel at suggestions that they conform to such rules as are commonly given to phthisical patients. Some even refuse to believe that they have any serious disease, because they say, if such were the case, "my own physician at home would have told me so, and he said nothing of the kind." Thus I have under my care at this time a young lady with all the usual signs of phthisis at the right apex, who utterly refuses to believe that there is anything of sufficient import in her case to make it necessary for her to stay more than a few months in Colorado, because her physician in the East told her that she had only "a little bronchial difficulty," and a visit there for a few months would be all that was necessary. She has been here for five months, and is making preparations to return to the Atlantic coast in April, as she has gained thirteen pounds and her cough has nearly ceased. The great probability is that she will be compelled to return here within a short time after her return.

I have seen many illustrations of this same error during the past eleven years. Most of the cases from the larger medical centres, and nearly all from the hospitals and clinics, which we see in dispensary and hospital work here are quite aware of the gravity of the disease for which they have left home, and are prepared to stay here permanently if necessary. Certainly private patients should not be deceived in a matter of so serious import through any motives of false delicacy or desire to avoid telling an unpleasant truth upon the part of the family physician. It is almost needless to state that it is much easier to treat those patients who have a full knowledge of the gravity of the situation than others. I think the physician, in sending a patient here, should speak plainly of the necessity of remaining for some time, or even, possibly, permanently. I have known several consumptives to regain health to such a degree as to lead them to believe that they could safely reside in the East, who, breaking down again, have returned to Colorado too late to again check the tuberculous process, so that the outcome has been a fatal one. With proper advice from the family physician in the East, many such patients would see the desirability of remaining here permanently rather than incur such risks by a return home.

A wider dissemination of the points so well treated in the paper of Dr. Knight would certainly be of inestimable value to the profession, and, through them, to the public.

I am yours very truly,

J. N. HALL, M.D.

ANOTHER FOUR-YEARS' COURSE.

UNIVERSITY OF MINNESOTA,
MINNEAPOLIS, December 30, 1893.

MR. EDITOR:—The Board of Regents of the University of Minnesota have extended the course of study in the College of Medicine and Surgery from three to four years, of eight and one-half months' duration for each course. The new schedule of requirements becomes operative in 1895.

PERRY H. MILLARD, M.D.,

Dean of the College of Medicine and Surgery.

Deaths reported 2,550; under five years of age 785; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 297, acute lung diseases 575, consumption 273, diphtheria and croup 121, typhoid fever 37, scarlet fever 37, diarrhoeal diseases 32, measles 20, whooping-cough 17, cerebro-spinal meningitis 15, erysipelas and malarial fever 6 each, small-pox 4.

From diarrhoeal diseases New York 12, Cincinnati 6, Cleveland 5, Brooklyn, Boston and Cambridge 2 each. From measles New York 9, Brooklyn and Milwaukee 4 each, Worcester 2, Boston 1. From whooping-cough New York 6, Brooklyn 4, Cincinnati 3, Boston 2, Cleveland and Pittsburg 1 each. From cerebro-spinal meningitis New York 6, Brooklyn 3, Cleveland, Worcester, Lowell, Lynn, Somerville and Fitchburg 1 each. From erysipelas Boston 2, New York, Cleveland, Pittsburg and New Bedford 1 each. From malarial fever Brooklyn 3, New York, Nashville

and Brockton 1 each. From small-pox New York and Boston 2 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending December 16th, the death-rate was 26.6. Deaths reported 5,275: acute diseases of the respiratory organs (London) 711, whooping-cough 172, diphtheria 122, measles 74, scarlet fever 66, fever 52, diarrhoea 47.

The death-rates ranged from 16.0 in Norwich to 36.4 in Bristol; Birmingham 21.2, Bradford 22.1, Cardiff 21.2, Croydon 24.9, Leeds 23.6, Leicester 29.4, Liverpool 31.8, London 31.8, Manchester 27.6, Newcastle-on-Tyne 21.2, Nottingham 31.9, Portsmouth 20.3, Salford 19.7, Sheffield 27.0, Sunderland 19.0, West Ham 25.5, Wolverhampton 19.2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 23, 1893, TO DECEMBER 29, 1893.

By direction of the Secretary of War, leave of absence for two months, to take effect on or about January 15, 1894, with permission to apply for an extension of one month, is granted MAJOR JOHN D. HALL, surgeon.

LIEUT. JOHN S. KULP, assistant surgeon, U. S. A., is relieved from further duty at Jackson Park, Chicago, Ill., from December 23, 1893.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FOUR WEEKS ENDING DECEMBER 16, 1893.

BAILHACHE, P. H., surgeon. Granted leave of absence for five days. November 28, 1893. To inspect quarantine ports. December 7, 1893.

PURVIANCE, GEORGE, surgeon. To inspect quarantine ports. December 7, 1893.

SAWTELLE, H. W., surgeon. To inspect quarantine ports. December 7, 1893. Granted leave of absence for three days. December 4, 1893.

AUSTIN, H. W., surgeon. Detailed as chairman, Board to amend and revise the Quarantine Regulations. December 9, 1893.

GASAWAY, J. M., surgeon. To proceed to Mobile, Ala., as inspector. November 22, 1893. To inspect quarantine ports. December 7, 1893.

MEAD, F. W., surgeon. Detailed as chairman, Board to examine candidates, Revenue Marine Service. December 9, 1893.

CARTER, H. R., surgeon. To proceed to Brunswick, Ga., for temporary duty. November 29, 1893. To inspect quarantine ports. December 7, 1893. Detailed as member, Board to revise and amend the Quarantine Regulations. December 9, 1893.

WHEELER, W. A., surgeon. Detailed as member, Board to revise and amend Quarantine Regulations. December 9, 1893.

BANKS, C. E., passed assistant surgeon. Granted leave of absence for seven days. November 22, 1893.

CARMICHAEL, D. A., passed assistant surgeon. To inspect quarantine ports. December 9, 1893.

WHITE, J. H., passed assistant surgeon. To proceed to Savannah, Ga., for duty. December 4, 1893. Detailed as member, Board to revise and amend the Quarantine Regulations. December 9, 1893.

CARRINGTON, P. M., passed assistant surgeon. To proceed to Baltimore, Md., for duty. December 9, 1893.

WILLIAMS, L. L., passed assistant surgeon. To proceed to Charleston, S. C., for duty. December 4, 1893.

PETTUS, W. J., passed assistant surgeon. Granted leave of absence for eleven days. To proceed to Buffalo, N. Y., for duty. December 4, 1893.

KINYOUN, J. J., passed assistant surgeon. To rejoin station Washington, D. C. November 24, 1893. Granted leave of absence for three days. December 4, 1893. Detailed as recorder, Board to revise and amend Quarantine Regulations. December 9, 1893.

WOODWARD, R. M., passed assistant surgeon. Granted leave of absence for seven days. To proceed to Cairo, Ill., for duty. December 4, 1893.

VAUGHAN, G. T., passed assistant surgeon. Detailed as recorder, Board for physical examination of candidates, Revenue Marine Service. December 4, 1893.

COBB, J. O., passed assistant surgeon. To inspect quarantine ports. December 7, 1893.

GUITERAS, G. M., passed assistant surgeon. To report at Bureau for temporary duty. December 6, 1893.

GEDDINGS, H. D., passed assistant surgeon. To proceed to New York, N. Y., for duty. December 2, 1893.

YOUNG, G. B., assistant surgeon. To proceed to New York, N. Y., for duty. December 4, 1893.

STIMPSON, W. G., assistant surgeon. To proceed to Detroit, Mich. December 4, 1893.

BURNS, B. W., assistant surgeon. Granted leave of absence for seven days. To proceed to Washington, D. C. December 4, 1893.

HOUGHTON, E. R., assistant surgeon. To proceed to Vineyard Haven, Mass., for duty. December 4, 1893.

ROSENAU, M. J., assistant surgeon. To proceed to St. Louis, Mo., for duty. December 4, 1893.

NYDEGGER, J. A., assistant surgeon. Granted leave of absence for seven days. To rejoin station Pittsburgh, Pa. December 7, 1893.

STEWART, W. J., assistant surgeon. Granted leave of absence for fourteen days. November 27, 1893.

STRAYER, EDGAR, assistant surgeon. Granted leave of absence for seven days. November 27, 1893.

OAKLEY, J. H., assistant surgeon. To proceed to Halifax, N. S., for temporary duty. November 24, 1893. To proceed to New York, N. Y., for temporary duty. December 14, 1893. To proceed to San Francisco, Cal., for duty. December 16, 1893.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — The annual meeting of the Society will be held at the Medical Library, No. 19 Boylston Place, on Monday, January 8, 1894, at 8 o'clock, P. M. Election of officers. Report of the Treasurer.

Dr. W. J. Otis will read a paper on, "External Piles and their Relation to the External Hemorrhoidal Veins." Discussion by Dr. C. B. Porter, Dr. H. L. Burrell and others.

Dr. Myles Standish will read a paper on, "Two Cases of Chancres of the Eyelid." Discussion by Dr. A. Post, Dr. E. Wigglesworth and others.

Dr. C. B. Porter will show patients illustrating results of some exceptional operations for exceptional surgical lesions.

Members are kindly requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., Secretary.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday evening, January 10th, at 8 o'clock, by Assistant Professor Ernst. Subject, "Advances in Bacteriology." Physicians are cordially invited.

RECENT DEATHS.

CHARLES M. CRESSON, M.D., a well-known chemist of Philadelphia, died December 27th, aged sixty-five years.

DR. S. GUTTMANN, of Berlin, the editor of *Deutsche Medicinische Wochenschrift*, died of influenza, December 22d.

BOOKS AND PAMPHLETS RECEIVED.

Epileptic Insanity. By James H. McBride, M.D. Reprint. 1893.

Fourteenth Annual Report of the Associated Charities of Boston, November, 1893. Boston. 1893.

Bacteriology in its Relations to Chemical Science. By Percy Frankland, Ph.D., B.Sc. (Lond.), F.R.S. Reprint. 1893.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland, Ninety-fifth Annual Session held at Baltimore, April, 1893; also Semi-annual Session held at Easton, March, 1892.

Spastic Senile Entropion cured by Canthotomy. The Treatment of Blennorrhoea Neonatorum. The Relation between the Eyes and Disease of the Female Genital Organs. By Boerne Bettman, M.D., of Chicago, Ill. Reprints. 1893.

The Measured Effects of Certain Therapeutic Agents, among which especially are Lavage, HCl, and Intra-gastric Electricity, upon the Secretory and Motor Functions of the Stomach in Cases of Chronic Catarrh (Glandular Gastritis). By D. D. Stewart, M.D. Reprint. 1893.

Chirurgie des Malades du Système Nerveux. M. le Professeur Charcot, Leçons du Professeur, Mémoires, Notes et Observations Parus pendant les années 1889-90 et 1890-91 et publiées sous la direction de Georges Guinon, chef de clinique avec la collaboration de MM. Blocq; Souques, et J. B. Charcot, internes de la clinique. Tome II. Paris: Aux Bureaux du Progrès Médical. 1893.

CASES OF ABDOMINAL SURGERY OCCURRING IN THE PRACTICE OF DR. J. COLLINS WARREN AT THE MASSACHUSETTS GENERAL HOSPITAL DURING THE WINTER OF 1893.

REPORTED BY CHARLES L. SOUDDER, M.D.

(Concluded from No. 1, page 5.)

CASE XIV. Exploratory laparotomy for tumor in the region of the kidney; recovery.

A negro, forty-two years old, single, always well with the exception of some rheumatism, six weeks ago complained of pain in the back and the left side of the abdomen. This pain has gradually increased, accompanied by nausea. Decubitus on the left side. The chest and spine, upon examination, were negative. There was a tumor in the left loin extending under the ribs, which moved slightly with respiration. The edge of the tumor was rounded, rather ill-defined, and not movable. The colon passed in front of the tumor.

Operation.—A curved incision was made from the eighth rib on the left, with the convexity down, as far as the left anterior superior spinous process. The colon presented. The patient having been tipped over on one side, the intestines were displaced so as to uncover the region of the left kidney. Irregular nodular masses (not connected with the spleen, but retro-peritoneal) were found adherent to the inferior vena cava and to the left iliac vessels and to the brim of the pelvis, these being enlarged lymphatic glands. Large and tortuous veins covered the mass in the region of the left kidney. An incision was made through the posterior wall of the peritoneum. The abdominal contents were displaced from over the tumor as far as the spinal column, clearly exposing this region. Owing to the presence of infected glands, it was found impossible to remove the mass without incurring too great risk, and further interference was advised against by those seeing the patient in consultation. Consequently, the abdominal wound was closed, and the patient made an uninterrupted recovery from the exploratory operation. He was heard from several months after he left the hospital, and was in fairly good health, the mass in the side still being present.

CASE XV. Pyo-salpinx; operation; recovery.

A woman, married, twenty-three years old. The catamenia have always been regular and painless until within the last two years, when there has been some irregularity. She has two children, the youngest being three years old. For two years there has been some swelling in the left side of the pelvis, which has caused a certain amount of pain. She entered the hospital on the medical side a few months ago, and was treated for a left salpingitis, and apparently improved while under treatment. Symptoms of pain in the left groin returned shortly after her discharge from the hospital. Examination upon re-entering found tenderness in the left groin upon deep pressure, and by the vagina the left cul-de-sac filled with a doughy mass which was tender.

Operation.—Trendelenberg position. A median incision found the omentum slightly adherent to the uterus and to a tumor in the left side. While freeing the adhesions the sac of the tumor was ruptured and a puriform fluid escaped, some of it into the abdominal cavity. The sac was removed, the abdomen washed with boiled water and drained by glass drainage in the

posterior cul-de-sac together with iodoform gauze. The tube was removed in two days, when the temperature was normal. She was discharged four weeks from the time of the operation, well.

CASE XVI. Exploratory laparotomy; carcinoma of stomach; recovery.

A man fifty years old, single, had always been well, although not very strong. Two months ago he had the feeling of weight in the left side, especially on rising in the morning; had lost some weight during this time, and had a dull, dragging feeling in the left abdomen. At no time has there been vomiting or distress after eating. His bowels have been fairly regular. He was pale, but not cachectic. In the abdomen, a hard, ovoid mass was felt in the epigastric region, which was movable, slightly irregular on the surface, seen to move with respiration, and was not adherent to the abdominal wall.

Operation by an incision parallel to the left costal margin. The stomach presented in the wound very much enlarged, with a tumor at the greater curvature reaching nearly to the pylorus. The tumor involved the inferior, posterior and some of the inferior and anterior walls of the stomach. It was nodular posteriorly and adherent to the transverse colon. No secondary nodules were detected in the liver. On account of the extent of the growth, which previous to the operation could not be accurately determined, further interference was advised against. The wound was closed with interrupted sutures.

The man made a good recovery from the laparotomy, and died about six months later from the disease.

CASE XVII. Double pyosalpinx; operation; recovery.

A woman thirty-one years old, married. Catamenia regular until the past few months. No children or miscarriages. Two weeks ago pain and soreness developed in the right ovarian region accompanied by tenderness in the right side of the abdomen; and upon vaginal examination bulging of the right vaginal vault, with fluctuation, was detected.

Operation.—Trendelenberg position. A median incision disclosed a tumor on the right side, the size of a small orange, adherent to the omentum and small intestine posteriorly. The tip of the vermiform appendix was adherent to the tumor. Half an ounce of foul pus and cheesy material escaped posteriorly upon an attempt to unroll the tube, which had become twisted backward. Upon removal of the tube, the pelvis was thoroughly irrigated with boiled water, a glass drainage-tube placed in the posterior cul-de-sac, and the abdominal wound partially closed. The drainage-tube was removed in one week. Two days later there was a sudden rise of temperature, and a phlebitis developed on one side. This gradually subsided, and the patient was discharged a few weeks later, the wound entirely closed. Shortly after the removal of the glass drainage the discharge became fecal, but remained so for only a day or two. Evidently a fistula formed, which rapidly closed without interference.

CASE XVIII. Abdominal hysterectomy for cancer of the uterus; death.

A woman fifty-one years old, married. Her grandmother died of "cancer of the womb." The patient passed the climacteric six years ago. For the past six months she has complained of pain in the left ovarian region, which has extended into the groin and left thigh. Vaginal examination found present an os uteri

three or four times the normal size, ulcerated, and the vaginal wall adjacent to the external os likewise ulcerated. An extension of the disease beyond the regions above named was not detected. Twenty-four hours previous to the operation the cervix was cauterized with the Pacquelin cautery and packed with iodoform gauze, the vagina being likewise packed. At the time of operation the vagina was irrigated with corrosive sublimate (1 to 3,000). The cervix was again cauterized, and an iodoform gauze tampon placed in the cervix. In the Trendelenberg position by median abdominal incision the uterus was exposed. The right and left broad ligaments were clamped and divided, the ovarian arteries being separately ligatured. The peritoneum was separated anteriorly from the bladder and posteriorly from the rectum. The vaginal wall was found, excepting in the area felt by previous examination, to be free from new growth. The vagina was packed with gauze up to the vaginal wound. A glass drainage-tube was placed through the abdominal incision down to the vaginal wound, and surrounded by gauze so that there was continuous gauze drainage from the abdominal wound to the vaginal wound externally. The infiltration of the vaginal wall below the cervix made the attempt to remove the disease through the abdominal wound exceedingly slow, and prolonged the operation so that the shock was necessarily very severe, and in her weak condition proved to be too great. The patient died twenty-four hours after her recovery from ether.

CASE XIX. Secondary laparotomy in presence of a suppurating sinus; death.

A woman, four months ago, complained of pain in the left ovarian region. There was some swelling in this region later. She remained in bed for ten weeks; and some ten weeks ago the doctor in attendance aspirated the swelling, getting no fluid. Two weeks later a purulent discharge appeared from the vagina and the rectum. A laparotomy was done soon after this. The left ovary and a pus-tube were removed. Several months later she returned to the hospital with a discharging sinus in the abdominal wound, and complained of great pain and tenderness just posteriorly to the anus. Under ether, an abscess in the region of tenderness posterior to the anus was opened, curetted and packed with iodoform gauze. It was found that there was a communication between the anal sinus and the abdominal sinus. The fecal discharge contained pus. Various attempts were made to close the abdominal sinus by means of curetting, canterization and various careful dressings.

With the hope of excising the abdominal sinus, and because of the presence of an encysted tumor of the right broad ligament and ovary which had developed since the left ovariectomy, a second laparotomy was performed. At the time of this operation very great precaution was taken to prevent infection of the fresh abdominal wound by the old sinus. To prevent this, the sinus was, previous to the operation, thoroughly cauterized, and the fresh wound very carefully protected. The left ovary and cyst were removed; the sinus was excised; and a glass drainage-tube was placed in the posterior cul-de-sac. The upper part of the wound was sutured. Three days later, after gradually increasing symptoms of peritonitis, the patient died.

CASE XX. A male deaf mute, thirty-six years old and married, entered the hospital with the history

of having been several times jaundiced; otherwise, he had always been well. A little over two months ago he was said to have had typhoid fever. The symptoms at that time were right iliac pain, vomiting, constipation followed by diarrhoea. Four weeks ago he had a similar attack, but less severe, since which time he has not been very well. A week ago a painful tumor was noticed in the epigastrium, tender upon pressure. The man was fairly well developed. His skin was slightly yellow. The sclerotic of the eye was white. The pulse was 110 and was of fair strength. The heart and lungs were negative. The epigastric swelling was about the size of a small orange. The movements from the bowels were of natural appearance. He slept fairly well. The temperature at midnight was 103.4°, and was normal in the morning.

Operation by an incision parallel to the right costal border. A cavity the size of the end of the thumb was opened and a small amount of puriform fluid evacuated. Several blind pus cavities were opened and curetted it not being possible to determine their exact anatomical boundaries. The bowel appeared to be healthy in the immediate neighborhood. The pus cavity seemed to be situated in a mass of inflammatory exudation. Gauze drainage was inserted and an absorbent dressing applied. In the right iliac fossa at the time of this operation there was very slight dullness. Three days after the operation this dullness in the right iliac fossa became more marked and pain in that region developed. One week after the first operation the patient was again etherized and an incision was made parallel to Poupart's ligament, over the dull and tender area in the right iliac fossa. A bile-stained fluid with light green flakes was evacuated, indicating a fecal fistula. The vermiform appendix was not found in connection with the cavity from which the fluid came. An opening was made in the colon during the operation, and this fecal fistula gradually closed, and the wound of the first operation closed rapidly; and the patient was discharged about five months after entering the hospital gaining in flesh and strength, apparently well, having had a normal temperature for four weeks previous to his discharge.

CASE XXI. General suppurative peritonitis following the reduction of an inguinal hernia by taxis; laparotomy; washing and drainage of the abdominal cavity; recovery.

For a year, the patient, who was a thin and yet fairly well developed man, had had a left inguinal tumor. Two days before entrance tenderness developed in the region of this tumor and an attempt was made by the attending physician to reduce it, which was supposed to be an inguinal hernia, by taxis. The tumor was reduced in size, and there was no impulse upon coughing. Because the symptoms of strangulation and intestinal obstruction remained, he was sent to the hospital, and it was decided to lay open the hernial sac, and a very peculiar condition of things was discovered. On laying open the sac, which had thick and rigid walls, it was found to be uninhabited, containing serum and flakes of fibrin only. A finger being passed through the neck of the sac into the abdominal cavity was, upon removal, followed by a gush of thick creamy pus. The first incision was enlarged nearly to the anterior superior spinous process of the ilium. Coils of intestine were thus exposed, which were found injected and covered with flakes of fibrin and pus. A finger introduced into the opening passed

to the hollow of the sacrum freely among the coils of intestine.

An abdominal incision through the umbilicus, half-way to the pubes, was now made for purposes of drainage of the entire abdominal cavity. Pus gushed from the median incision. The entire abdominal cavity was flushed with warm water through the median incision, the wash-water passing out of the left inguinal opening. Glass drainage-tubes were inserted through both incisions to the hollow of the sacrum. A counter-opening was made in the left loin, through which two large rubber drainage-tubes were passed from the median incision. The wounds were packed about the tubes with iodoform gauze. The operation relieved the general peritonitis, but the symptoms of obstruction remained; consequently after six days the presenting coil of bowel, which proved to be small intestine, was opened in the left inguinal region with great relief to the distention. A discharge of feces by both rectum and fistula followed. The median abdominal wound healed kindly, but considerable difficulty was found in preventing the digestion of the skin about the opening of the fecal fistula in the left groin. The skin immediately surrounding the fistulous opening was protected by means of absorbent cotton and oxide of zinc ointment, which was allowed to dry, forming a firm crater-like opening around the fistula. A special nurse was in constant attendance, and removed the discharge from the fistula as fast as it appeared at the bottom of the crater. Gradually under this very careful attention the fistula healed. Dr. Warren decided not to attempt closure of the fistula by suture, but to trust to healing by granulation, as the fistulous opening was situated at the bottom of a deep wound, the conditions differing materially from those present in cases in which the bowel presents close to the abdominal wall in artificial anus. The man left the hospital in splendid physical condition, with the fistula healed, about three months after the operation.

Remarks.—This case may be very well regarded as one of most desperate character. A suppurative peritonitis was probably caused by an inflammation of the strangulated loop of intestine which had been reduced out of an old and rigid sac. It illustrates too, the value of efforts to relieve general suppurative peritonitis by operative procedure.

CASE XXII. Chronic appendicitis; recovery.

A man, thirty-five years old, married, had always been well previous to his present illness, four months previous to the entrance to the hospital, when he had a sharp attack of pain across the middle of the abdomen, was constipated, but did not vomit. This attack lasted for a few days, and he went away as a sailor to sea, since which time he has had one other similar attack. At the time of entrance some resistance was felt to the right of the epigastrium. He had considerable pain in the right iliac region and fulness in the right flank, where there was dulness and increased resistance. There was very great tenderness present.

Operation.—An incision was made parallel to Poupart's ligament upon the right side. The muscles, as divided, appeared oedematous. An abscess cavity was opened, containing a small amount of puriform material. The wall of the abscess cavity presented the appearance of sarcomatous tissue. The wound was thoroughly washed and packed with iodoform gauze. Six weeks later a tender spot, with some

swelling, was felt just below the right false ribs. Under ether, an incision here evacuated eight ounces of foul pus. One day later a second fluctuating area developed just above the last incision, and was opened, giving exit to four ounces of pus. The exploring finger entered an abscess cavity behind the liver. Three weeks later, having a continuous pus temperature and growing weaker, another operation was done, laying open the previous incisions, which had not yet entirely healed. The patient is still in the hospital, the old sinus discharging.

CASE XXIII. Movable kidney; nephrorrhaphy; recovery.

A woman, married, in good health, has had since her last child was born, sixteen months ago, distress in her abdomen in the region of the stomach, accompanied by a dragging feeling. Has lost some flesh of late. Examination found a rounded movable tumor in the right hypochondrium, pressure upon which caused pain in the epigastrium. The tumor is easily moved. The knee-chest position permits more ready access to the tumor, which resembles the kidney in shape. An operation for the fixation of the kidney to the posterior abdominal wall was advised, as offering the best chance of relief from the symptoms. The operation of nephrorrhaphy was done by an incision four and one-half inches long in the right flank, starting two and three-quarter inches from the spine, one-half inch below the twelfth rib, and extending outwards towards the iliac crest. The muscles were divided in the full length of the incision. The edge of the latissimus dorsi slightly encroached on the wound. The perinephritic fat was found. All bleeding points were tied, and the fat tissue incised. Pressure over the abdomen caused the surface of the kidney to present in the wound. Five silk sutures were taken through the fibrous capsule and a little of the kidney substance, and then through the lumbar fascia and erector spinæ muscles. Two of the sutures were slightly above the middle of the kidney. The wound in the abdominal muscles was closed with three silk sutures, leaving some of the perinephritic fat bulging between them. The skin was sewed with interrupted silk sutures; baked gauze dressing; swathe. The condition of the patient at the end of the operation was good. The recovery was uneventful. The patient, after four weeks' recumbency, was allowed to walk about, wearing an abdominal binder of flannel.

CASE XXIV. A man, sixty-five years old; carcinoma of rectum; Littré's operation; recovery; condition six months after operation.

The patient was small, always well and strong till a year ago, when he noticed pain in the rectum on defecation. He has been troubled with frequent micturition for the last six months. Examination showed the patient to be well developed, but thin and somewhat cachectic. The radial and temporal arteries were atheromatous. By rectum, the prostate was found to be somewhat larger than normal and tender. Internal sphincter was rigid. Just above it was a tender spot; no induration was felt. The rectum was ballooned. Externally, in the left iliac region, a hard band was felt; it was tender, and corresponded to the site of the sigmoid flexure. Rectal tube passed readily eight inches up the bowel. Small movements resulted from high injections of glycerine and suds.

On the 24th of the month the operation was done. An incision three inches long was made in the left in-

guinal region, two inches above Poupart's ligament, starting just inside the line of the anterior superior spine. On opening the peritoneum, the sigmoid flexure presented, much distended with gas, and was sewed to the margins of the wound with three fine silk stitches on each side for a distance of one and one-half inches above and below the loop of bowel; the lips of the incision were united with three deep silk sutures.

On the 25th he had a good night; little pain or nausea. The gauze was slightly stained. Some three or four feet of small intestine were found protruding from the wound. Under ether the escaped bowel was cleansed with boiled water and replaced.

The man made a good recovery. The artificial anus was a success. Daily formed movements occurred. He had much less pain and ate well. After six weeks he was discharged from the hospital, greatly relieved.

Six months after the operation, December, 1893, he was examined, and the general condition was found to be much improved. Said he could walk a mile with ease. He had formed movements through the artificial anus, and some liquid always passed per rectum. He had very little pain, mostly in the left lumbar region. He had no pain in the leg. There was a tendency for superficial abscesses to form around the fistula, which discharged slightly and then dried up.

The foregoing cases serve to illustrate the variety of abdominal surgery occurring in a single service at the Massachusetts General Hospital, and are suggestive of the methods of procedure in certain obscure and difficult cases.

In every instance great care was exercised in the preparation of the field of operation, the instruments used, the ligatures, suture and dressing material. The hands and arms of the operator and his assistants were first scrupulously cleansed with soap and nail-brush, then with a saturated solution of permanganate of potash, decolorized with oxalic acid and peroxide of hydrogen and soaked in a solution of corrosive sublimate of the strength of one to two thousand. In spite of the great care exercised in the counting of sponges, one was left in the abdominal cavity of one of the fatal cases.

There were in all twenty-four cases, as follows:

Solid tumor of the ovary	1
Multilocular cyst of the ovary, single	2
Salpingitis	3
Congenital liver hernia	1
Cyst of the broad ligament	1
Appendicitis, acute	3
Appendicitis, chronic	1
Salpingitis, double, tubercular	1
Carcinoma uteri	1
Carcinoma uteri (hysterectomy)	1
Cysto-adenoma of the ovary	1
Intra-ligamentous ovarian cyst	1
Exploratory laparotomy	2
Sinus of abdominal wall	1
General suppurative peritonitis	1
Movable kidney (nephrorrhaphy)	1
Carcinoma recti (Littre's operation)	1
Obscure abdominal abscess	1

There were three deaths, making a mortality of twelve and one-half per cent.

A NOVEL CHRISTMAS ENTERTAINMENT.—A daily paper relating the events at the annual Christmas party at the poor-house of a neighboring city, says: "An excellent entertainment by local talent was given. Among the features was the treating of several of the inmates who have rheumatism by a magnetic healer."

OBSTETRICAL ASEPSIS.¹

BY JOSEPH PRICE, M.D., OF THE PRESTON RETREAT, PHILADELPHIA.

It is customary to come to Boston to listen. The one who comes here to talk should be sure he has something to say. This fact gives me embarrassment. I do not bring to you those graces of classic culture attained in old Harvard's college halls. I have no surprises in the shape of new facts; and my only logic will be that with which my experiences, observations and reading supply me. The same may be yours, and in giving mine I only strengthen and confirm yours. Within myself I represent but little; yet with you I enjoy the proud privilege of sharing in the common triumphs of our profession. A distinguished novelist, one who gives us in our brief leisure delightful entertainment, sitting talking with a Boston friend on a public occasion in one of your great halls, remarked, on the entrance of one of your illustrious citizens, orators and statesmen—a man he did not know, had never seen before: "There goes one of God's noblemen." It is with such men I would be in touch for what they are to me, for what they have for me, for the strength such contacts and associations renew in me. If there be a human calling, service or profession that commands only the best, all the forces of innate and cultured manhood, all that distinctively makes up the nobleman, it is that of medicine and surgery.

It may impress the profession that I urge with a relentless persistency the importance of cleanliness in maternity work, and in all surgery, special and general. For this urging there is no need of apology. It is one of the lines in which our efforts run no risk of extravagance. From time immemorial there has been much discussion of dietary precautions, drink, climatic influences, dress, exercise, morals. Much that is wise has been said, and much that is otherwise. Yet the subject of cleanliness has never been given that consideration in all its many bearings its importance to the general health demands, and that is yet more imperatively demanded in all cases where medical and surgical treatment is involved. No matter how scrupulous our purely personal precautions may be to render the patient less liable or susceptible to infections, if the influence of environments are against us, our success cannot be complete. But science is going on correcting our mistakes and evolving for us new truths. It is not my purpose to deal with the abstruse questions of the science of obstetrics. Our increased knowledge of anatomy and of the phenomena of labor has cleared away many of our difficulties.

A high mortality in a maternity or in private obstetrical practice is simply evidence of bad management. Success in our maternities and in private obstetrical practice requires scrupulous attention to cleanliness. This cleanliness should begin with the physician, with his person, his clothing; his hands should not be in mourning. There should be no room for the application of the witticism of Charles Lamb to his companion in the game of cards: "If dirt were trumps you would hold a full hand." This cleanliness should extend to the nurse and with equal scrupulousness to the patient. In considering what cleanliness has done for maternities, it is interesting to note the views of some of the men who have filled important positions in our great schools as teachers.

¹ Read before the Obstetrical Section of the Suffolk District Medical Society.

Professor Hodge says: "The result of the whole discussion will, I trust, serve, not only to exalt your views of the value and dignity of our profession, but divest your minds of the overpowering dread that you can ever become, especially to woman, under the extremely interesting circumstances of gestation and parturition, the *minister of evil*; that you can ever convey, in any possible manner, a *horrible virus*, so destructive in its effects, and so mysterious in its operations as that attributed to puerperal fever."

Professor Meigs says: "I prefer to attribute them to accident, or Providence, of which I can form a conception, rather than to a contagion of which I cannot form any clear idea, at least as to this particular malady."

That is a pitiable, professional courage which makes Providence responsible for these calamities, when they are the result of unskilful work, neglect of important details of treatment, of the common-sense lessons of practical obstetrics, and of sleepy, lazy, slovenly, sloppy nursing. If you should tell one of that class of gentlemen who shift their bad work off on Providence, that their results were caused by filth, by inattention, bad nursing, unskilful treatment, their reply would probably be that of Emerson's school boy to the teacher: "That letter is A," said the teacher. "A," drawled the boy. "That is B," said the teacher. "B," drawled the boy. "That is W," said the teacher. "The devil it is," exclaimed the boy, "I thought it was something else."

But listen to the good sense of one of your New England teachers, Oliver Wendell Holmes: "The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses."

Gordon, as far back as 1795, wrote: "I arrived at that certainty in the matter, that I could venture to foretell what women would be affected by the disease, upon hearing by what midwife they were to be delivered, or by what nurse they were to be attended, during their lying-in; and almost in every instance, my prediction was verified."

Since Gordon has made mention of the midwife, I will say that I am not so sure that she is a boon to the physician. She may serve to prevent his sleep from being disturbed, but I am uncertain as to her success in saving the lives of mothers and children. They rarely come from the more cleanly, refined and educated ranks of society. As a rule, they are without pretension to training for such responsibility; and the risks are those that come of ignorance and all that follows in its train. The nurse attending in lying-in cases should be scrupulously clean by habit in everything that pertains to her person, be of some refinement and culture, have had a prolonged period of pupilage. In the service of every obstetrician there should be the trained nurse.

I am not stating a modern medical experience when I state that we cannot expect good results in a stinking atmosphere, by breathing air filled with the volatile refuse of the human body, the effluvia of sewers. It is the stealthy, lurking poisons, those in ambush, our cleanliness must reach. It would be interesting as well as valuable to us if we had reliable statistics of the many cases of septicæmia caused in young and healthy women by the impurity of the air of the room in which they are confined, by the septic influence of chronic pyæmia and malignant disease. Cancer of the stomach, all discharging malignant sores are a source

of danger when in close proximity to a lying-in woman. We have passed beyond questioning drain and sewer-gas poisoning. And in this connection we must get beyond simply interrogating tables of mortality. The inquiry should be extended as to how many women barely escape with their lives, and thus escaping live out miserable lives, useless as wives and mothers, a burden to their families or the community.

There can be no restricting the broad meaning of the term "cleanliness." It applies with strong force to person, to clothing, to hands, to finger-nails, and with yet stronger force to personal morals. As physicians we are the supremely trusted of society; we are the missionaries of a humanly saving Gospel, the one supreme command of which is, "Be clean." When we have clean men—clean morally; men with high self-control, the energy and intensity of whose moral lives diffuses itself through—permeates—their very clientèle; then we shall have less syphilitic complications. Improved morals and healthful physical conditions go together. And there is no form of cleanliness more strongly and devoutly to be hoped for. We have much to do with the underlying, the better life-principles of our social fabric. We communicate what we are; we dominate in proportion as our own cleanliness is beyond reproach. The alliance of clean morals with the forces of our science, with our improved arts and methods, will greatly aid in reducing the sum of human suffering, and relieve us of much of that severe tension, that weighty, wearing burden of anxiety inseparable from much of our work. That general practitioner or surgeon who lightly takes a case into his hands for treatment, no matter what its nature or character, who does not realize that it appeals to the best genius of his science and art, who does not feel the motor force of solicitude as to issue, is unworthy of a place in our profession. There should be done with him that which your heroic—though, from the Briton's standpoint—naughty forefathers did with the tea: he should be thrown overboard.

I have been speaking of cleanliness in obstetrics, not as to its wider possibilities in the matter of general health. In obstetrics it is local uncleanness and not so much with general that we are concerned. Since health is one of the conditions of human happiness, there is nothing in which we should have so much and so enlightened and active an interest as in the health of our communities. Suppose you take note of the dumping-grounds within your municipality or its environs, of the particular localities where there are cesspools or putrescent collections of solid and liquid matter, and reckon the percentage of the sick and enfeebled, and the mortality within the same and in contiguous neighborhoods, and compare these with other localities where there is a rigid observance and practice of wise, scientific, healthful sanitary conditions. The result would be startling. It is not possible though to so analyze the statistics of mortality as to give due credit to filth.

Science and experience confirm the fact that under filthy conditions we run great risks and have deaths, and that under opposite conditions we have good results. We know that cases of zymotic disease are much more frequent and numerous within certain filthy localities or areas than they should be, than they are in others where sanitary conditions are as nearly perfect as it is possible to make them, where there is a more strict observance of the plain, conservative laws of hygiene.

An important question with physicians should be, How many diseases are preventable by absolute cleanliness, by rigidly enforced sanitary regulations, by rules that are the very transcripts from nature, those approved by the best science? We know that many diseases have their birthplace exterior to the human body. Many sad, horrifying experiences convince us that many diseases have their origin amid controllable conditions. The fact that many diseases go on more actively in summer than during any other season of the year can be credited to no other fact than that organic decomposition goes on more rapidly then than in other seasons.

The general public has not yet grown to a full appreciation of the beneficence of sanitary science and the necessity of the scrupulous practice of all its lessons. Such an appreciation will only be reached through enlightened, wisely directed and energetic efforts on the part of the medical profession. The extent of the responsibility of the profession in this matter cannot be overestimated or too strongly pressed home. We claim to be a self-governing people, to make our own laws, to have incorporated in them our own wills: their wisdom must be taken as the reflex of our wisdom. If they are inadequate or faulty in their provisions or they fail of execution, it is not difficult for us to trace a large share of the responsibility. The general public should be educated up to the understanding that there is no politics in disease, and that our sanitary authorities should be representative of the highest intelligence and scientific culture and research. They should be above the reproach of having any politics in their motives or their methods; they should be typical representatives of the best morals, intelligence, public spirit and enterprise to be found in the community, irrespective and regardless of party affiliation. They should not be appointed simply because they are the Governor's, the Mayor's or some City Father's friends, but for their clean morals and their brains. If disease only affected the small district or ward politician, no matter of what "kith and kin," we would say, Let the filth pile up, dump the garbage at the doors, dam up the sewerage, and be cheerful while the funerals pass. But these tough men live on while filth-diseases destroy the worthy and good.

The condensing of populations into close neighborhoods renders cleanliness and perfect sanitary administration difficult. This fact renders it the more important that the responsible work should be placed in intelligent hands.

My experiences and observations have not been confined to maternity hospitals, but have extended into the homes of the well-to-do, the refined and educated. They had their beginning in alleys and courts densely crowded with the poor; our best lessons, those of most practical value, we gain there. These unfortunates in their dire distress ask no questions, imply no doubts, but trust; and we put to severest test our resources, our best skill. The lessons we learn there, we carry into the sick-chambers of the more fortunate. My experiences and observations, therefore, have not been entirely drawn from or confined within the limits of a maternity hospital. I speak for maternities for the reason that I believe that there should be more of them, and that they should be better sustained. They should be established, and put under the best of management, in every manufacturing and mining town, in every centre of any considerable population.

It has not been long since the propriety of closing maternity hospitals in some of the cities of Europe was seriously discussed; by reason of their mortality they were condemned. This was very prominently a fact in Dublin not many years since, and was aimed specially at the great Dublin Hospital. The beneficence of the maternity hospital prevailed over ignorance and prejudice. They are a great source of education in one of the most important departments of medical education; but they have grown to be recognized to be something more than educational, as humane institutions and the most Christian of charities.

It will always be difficult to obtain full and accurate statistics in private obstetrical practice, such statistics usually being derived entirely from memory, no careful record being kept. It is also difficult to always obtain truthful and reliable statistics from many hospitals. In the matter of the data bearing upon this subject, we cannot do better than quote so eminent an authority as Dr. Matthews Duncan, of England.

"To judge the hospitals aright, the proper course is, evidently, to take the best as an example. We cannot justly condemn all hospitals because in that of Leipzig the mortality is one in seven. We do not condemn ovariotomy because in the hands of some surgeons the mortality of it is nearly cent. per cent. We take the practice of the best ovariotomists to judge by. To judge of hospitals, let us take the Dublin Hospital as managed by Collins. In seven years he had 16,654 births under his care. The mortality of mothers was one in one hundred. When I take this example, I must add that I regard it as not the best, but as a fair, handy and well-known example. If all hospitals are to be condemned, then this one must be condemned (1 in 100). And I ask any obstetrician to come forward and cast the first stone. Several have already come; but, in future, if any one is bold enough to come, he must tell us what is the mortality in his own practice, and he must consider whether or not his own practice is comparable with that of a hospital which receives the poorest, having among them drunkards, the diseased, the seduced, and also cases of difficulty in higher relative proportion than in ordinary practice. The great Dublin Hospital, then, can show a mortality of 1 in 100. Sir James Simpson has published the mortality of two years of his practice; it is 1 in 45, at least. Dr. Cross had in his practice a mortality of 1 in 98. I have had a mortality in mine (Duncan's) of, at least, 1 in 105. Dr. McClintock's is 1 in 108. Dr. T. E. Beathy's is 1 in 121."

When we get really trustworthy and comparable figures, how does hospital practice look? I, at least, cannot condemn it. I see no reason to doubt that it may be, and has been good enough to compare with any kind of practice. I know no good, large and unexceptional data of deliveries, which show results that are better than those of Dr. Collins in the Dublin Hospital.

I would here acknowledge an individual professional debt, one shared in by the profession at large — to that grand old man, the "Professor and Autocrat of the Breakfast Table," Dr. Oliver Wendell Holmes. We honor and love him for the delights we find in all the pages of his books; for his many witticisms pointed with great common-sense; for the elegant diction, clothing the great thoughts, veining every page he has written. We honor and love him the more for the great truths he has taught us, truths vital and guiding

in the practice of our profession. When all that was ever done, uttered or written, by a Hodge or a Meigs has passed out of human memory, ceases to be even honored by traditional mention, that described by Meigs as the "jejune and fizeuseless dreaming of the sophomore writer" will live on. The grand old "sophomore writer" lives to-day in a bright, cheerful old age, filled with the sense of a useful and nobly spent life, that his fellow-beings are the better for his having lived; honored of two worlds, and looking with assured trust and confidence into the next. What a depth of truth, what a deep touch of pathos in the following words of your loved New England Professor! They are words that should be deep graven in the memory of every obstetrician: "No man makes a quarrel with me over the counterpane that covers a 'mother, with her new-born infant at her breast.'"

TREATMENT OF SMALL-POX BY NON-ADMITTANCE OF THE CHEMICAL RAYS OF LIGHT.

BY RICH. HOGNER, M.D., BOSTON, MASS.

An article in the Swedish medical journal *Hälsö*, November 30, 1893, over the signature "F——" sums up what is at present known about the medico-practical significance of the ultra violet rays of light and begins with a mention of Prof. J. E. Widmark's article on "The Influence of Light on the Skin," published in *Hyggea* (Stockholm, Sweden), 1889, in which Widmark demonstrates that eczema (erythema) solare is caused by the ultra violet (chemical) rays of light from the sun, and in which he, at the same time, advances the opinion that this eczema must not be confused with eczema caloricum, which is caused by the influence of great heat. The latter usually develops instantly and hastily, and traces of it disappear with comparative rapidity; whereas the sun-erythema, on the contrary, first develops several hours, or even a day after exposure, is of longer duration, disappears after several days by scaling, and leaves a pigmentation.

In 1858, Charcot observed that the electric arc-light could cause a skin disease which greatly resembled sun-eczema. In the meantime it was reserved for Widmark to strengthen, through a series of exact experiments, the observations of Charcot, and to prove that the ultra violet rays of light played the chief part in the cause of eczema electricum. Finally Widmark quotes from Veiel the history of a woman who suffered from sun-eczema for a long time, which reappeared as soon as she came into the open air, even if the sky was clouded. She was not troubled by heat from a stove or intense lamplight and Veiel concluded, therefore, that the chemical rays were the cause. After Veiel had learned from a photographer that he succeeded best in excluding chemical rays of light by the use of dark red paper, he allowed his patient to go out in full sunshine when wearing a red veil. The experiment succeeded and she could remain out-of-doors for forty minutes at a time without inconvenience.

Through his experiments Widmark arrived at the conclusion that the ultra violet rays (whose caloric energy may be so little that it can scarcely be measured by the most sensitive instrument, and whose power of irritating the retina is so weak that it is only perceived by our eyes when the rays of light are en-

tirely shut out), do develop pathological processes on the surface of the body, in case they are of sufficient strength.

In the *Hospitals Tidende*, No. 27 (published in Copenhagen), appears an article concerning "The Influence of Light on the Skin," by Prosector N. R. Finsen. After relating Widmark's experiments and proofs that the ultra violet rays of sunlight produce eczema solare in an acute form, some observations of Unna are related, which show that pigmentation in such a case is the result of a chronic influence from the same light, and forms a protection for the skin. It is further shown from a paper in the *Lancet* for 1867, by C. Black, that the latter has employed non-admittance of daylight with remarkable success during a small-pox epidemic, and that Black's observations were endorsed by Barlow and Waters (*Lancet*, 1871).

On the strength of the foregoing and our present knowledge of light as an irritant of the skin, Finsen advanced the opinion that in place of complete exclusion of daylight from the small-pox patients, a closely-drawn red curtain or a window of red glass may be used.

The proposition was soon put into execution; for only one month later, Dr. Lindholm, of Bergen (Norway), wrote to Finsen as follows: "I am pleased to be able to tell you that the proposed treatment of small-pox seems to have a remarkable effect, inasmuch as the oedema disappears rapidly, and the suppurative fever does not appear at all." This applied to ten unvaccinated cases.

In No. 44 of the same journal we find a further statement of the small-pox epidemic in Bergen, related by Dr. Svendsen, where the following occurs: The clinical diagram of the cases treated in this way shows the following deviations: "The stage of suppuration was avoided; there was no increase of temperature, no oedema, etc. The patients went from the vesicular stages, which seemed to me somewhat protracted, immediately to convalescence and were spared disfiguring scars." Although the material is indeed small, from which to prove the efficacy of this mode of treatment in all cases, Dr. Svendsen considers that the results call for further trials of this simple and harmless method. But it must be strictly employed and before the suppuration stage begins; later its use would be of no avail. A couple of test cases where the patients were exposed to daylight, after excision began everywhere except on the hands, showed that the vesicles there began to suppurate and left small scars.

In the same number of the *Hospitals Tidende*, Prosector Finsen writes — in a new and longer treatise, — "Concerning the Injurious Influence of Chemical Rays on the Animal Organism," after having briefly recalled the contents of the preceding article: "The so-called chemical rays which have their place principally in the blue and violet, but especially in the ultra violet portion of the spectrum, are the most frangible rays of light; in them the chemical influence is strongest, but the caloric influence at a minimum. The condition at the other end of the spectrum is just the reverse; there the red and ultra red rays are the least frangible, there the caloric influence is strongest and the chemical influence at a minimum."

These two kinds of rays, the red and the violet, being representatives of the two extreme ends of the spectrum, seem also to exert very dissimilar physiologi-

cal influences. The violet seem to act with more intensity, at least their influence is more obvious to the eye; and when one collects observations on the influence of monochromatic light on different organisms and combines them, one finds that there seems to be a common quality in all living organisms (perhaps with the exception of vegetable growths), so that they are affected disagreeably, even injuriously, by chemical rays whenever these exist in sufficient intensity.

As proof of this assumption, reference is made to the power of light in destroying bacteria, in doing which the chemical rays are most active. On the light-shunning dew-worm red light acts as darkness, violet as daylight. The same is the case with the proteus.

The shiftings of color on the chameleon under the influence of light depend on the fact that those cells of the skin which are rich in pigments lie near the surface when in light, but deeper when in darkness. Paul Bert has also found that neither red nor yellow light works upon these cells, but that both the blue and violet light act so much the stronger. It has even been shown that horses and horned cattle get erythema from the chemical rays on such portions of the body as lack pigment—a fact which Widmark had previously proved concerning rabbits. The injurious effect of the chemical rays on human beings has already been stated.

The acute effect (which is discernible macroscopically) presents all stages from slight irritation and redness to strong inflammation with blisters which contain liquid, and desquamation of the epidermis. The stages depend on intensity, light and the quality of the chemical rays; and in this connection it is noticed that of the artificial lights, lamplight contains relatively fewer, but electric-light relatively more chemical rays than sunlight. The stage further depends on the duration of the influence and on the greater or less pigmentation of the skin. Unlike every other inflammation which lasts the same length of time it leaves pigmentation after it. It is distinguished from inflammation resulting from heat by its not appearing immediately after exposure to that which causes it, and that it reaches its climax a half or a whole day later.

That the skin is most easily affected in spring depends, says Finsen, on the fact that during winter time the pigment wears away with the epidermis, and the skin is left less protected in consequence. The bridge of the nose and the cheeks are most affected. But with glacier tourists who are subjected to reflected light, the rays coming from below, the skin under the nose and chin is most affected. Boat-racers get a typical sun-erythema on their bared arms during the spring, and the militia on their faces at the same season.

The Russian physician Maklakoff brought on a severe erythema like that of the laborers when he witnessed a smelting of metal by means of five hundred accumulators. This erythema could not be ascribed to development of heat, which was relatively slight, which proves what Professor Widmark said of the effect of the chemical rays on the skin (as previously stated) to be true; that is, that it is not the caloric rays, but principally the ultra-violet ones, that cause the well-known effects of light on the skin.

Following this, Finsen attempts to search out the histological processes of the inflammation in question. To this end, he has made use of tadpoles, whose tails

he examined under a microscope after exposing them to sunlight from which the caloric rays were excluded; thereupon the usual signs appeared in and around the capillary vessels, but, besides this, the blood-corpuscles changed from oval to round. It is well known that light acts as a contractor on living protoplasma. Finsen thinks the influence of light on the capillary vessels should be taken as explanation of the inflammatory process in the skin. He bases this assumption first and foremost on the fact that the pigment which forms a means of protection from the chemical rays lies alongside the capillary cells, and, further on, the fact that no living tissue absorbs so much light, and at the same time such a mass of violet rays, as the blood.

"Now that we have seen," says Finsen, "what strongly acute affections the chemical rays can produce, we can easily understand that even several chronic skin troubles stand in relation, both as to etiology and its subsequent course, to these rays. Of such diseases, we already know pellagra, xeroderma pigmentosum and Hutchinson's summer prurigo. But as the chemical rays have been so recently recognized as irritants of the skin, it is possible that the list of such diseases will be extended.

"In another category may be placed such diseases as, without being etiologically dependent on the chemical rays, are unfavorably affected by them, and among these we should place small-pox. It is impossible to say at present whether in time we shall come to reckon with the latter other exanthematic diseases or skin diseases, but it seems not impossible when the chemical rays can act so injuriously upon a healthy skin. As to small-pox, we see by concurring reports, and most recently that of Dr. Svendsen, that when the chemical rays are shut out the vesicles dry up without becoming purulent, and thus suppurative fever is avoided, in consequence of which the disease is less dangerous, of shorter duration, and, when ulceration is eluded, less painful. By this means scarring is obviated."

It seems to be undisputable that on the exclusion of the chemical rays depends the non-purulent character of the vesicles and the changed character of the disease. Still the author declares that a complete explanation cannot at present be given. But while awaiting further examination of the process, he thinks it may be stated thus: the power of chemical rays to produce irritation acts as a plus quantity, it increases already existing skin inflammation and prolongs it, so that the conditions become more favorable for the development of micro-organisms.

As the proposed treatment for small-pox is not, according to the author, a special thing for this disease, but a new therapeutic principle, he recommends physicians, especially those treating epidemic diseases, to try its effect on other exanthematic diseases, such as measles, scarlet fever and erysipelas.

As a last addition to this subject of treatment of small-pox, an article appeared in *Hospitals Tidende* for November 8th, written by the well-known medical historian, Prof. Julius Petersen. "The interesting communications," he writes, "of Prosector Finsen and Dr. Svendsen have strengthened for me, as medical historian, the old rule, which I often advanced, of the constant working in a circle in medicine—a circular movement which consists of the reappearance of the old permanent principles, though newly applied and fortified through the more exact investigations of the present." Then he tells how it was customary, even

in the Middle Ages, to make use of red curtains and cloths in the treatment of small-pox. For example, in the "*Rosa anglica*" (about 1300) of the English royal physician Gaddesden, we read that when the king's son had small-pox "everything used around his bed was of red, and that it is a good cure. I cured him without pock-marks (*sine vestigiis*)."

When small-pox was rife in Denmark in the seventeenth century, Thomas Bartholin spoke of this recognized method of treatment; and in the eighteenth century Fouquet wrote from Montpellier that in his childhood, "*on vetaissait les petits vérolés de trap ecarlate et que l'on les tenait dans les lits formés des rideaux de la même étoffe.*" Further on, in the "enlightened period," the method was denounced as superstition, and was forgotten entirely by historians of medical practice. And there was no rational foundation for its use. "It is," says Professor Petersen, in closing, "investigators of the present day who have the whole honor of having found an undeniably more satisfactory and exact scientific foundation for the old empiric fact."

Clinical Department.

A CASE OF UTERINE TUMOR.¹

BY DR. E. W. CUSHING, BOSTON.

Miss E., of New Hampshire, forty years old, came under my care this winter with the following history:

Was well until six years ago, when a small tumor was noticed, which increased gradually. There never was any menorrhagia. She consulted various physicians, both at home and in this city; but from all she received advice to wait and see if the tumor would not disappear at the menopause. It has grown steadily and rapidly, however, until now her condition is very serious — health broken, heart rather feeble, digestion impaired, respiration impeded. She realizes that she cannot live much longer without surgical relief.

At present the patient is slight in figure and much emaciated. The abdomen is occupied by a large tumor, which is so soft as to give an indistinct sensation of fluctuation. The pelvis is filled with the lower portion of the tumor, which is smooth and not very hard, and continuous with the uterus.

Diagnosis, probably a soft myoma.*

On opening the abdomen the tumor was exposed, and as it seemed too soft for a myoma it was punctured with a trocar, but no fluid escaped. Incision was prolonged, and the upper part of the tumor was delivered through the opening. It was seen that the growth had lifted the layer of peritoneum from the posterior abdominal wall, and had separated the folds of the broad ligament; so that the large intestine appeared to be adherent to the tumor high on its posterior surface. The apparent adhesions, however, were really the insertion of the mesentery, as is often seen in such cases, but not always understood at once.

The outer part of each broad ligament, with the ovarian arteries, was tied off; but it was impossible at this stage to tie the uterine arteries, as the tumor could not be lifted from the pelvis. On each side were several great veins, each larger than a lead-pencil.

To free the tumor, the thin capsule of peritoneum and uterine tissue was divided by a circular incision,

some four inches above the brim of the pelvis and well clear of the mesenteric insertion. On the left side a little spurt of clear fluid, from what appeared to be a large vein, was noticed.

By enucleation of the tumor and clamping of vessels the growth was lifted from the pelvis, and an attempt was made to secure the uterine arteries for intra-peritoneal treatment of the stump; but, owing to the bulk of the tumor and the size and variety of the vessels, this method was abandoned, and a rubber tube was used as a constrictor, the tumor cut away, and the stump treated extra-peritoneally, as usual.

When the tumor was removed a deep cavity remained bare of peritoneum on each side, so that at the bottom of each side of the pelvis the iliac vessels were visible. On the right was a large, tortuous tube, dilated in some places more than others. This had been carefully avoided in tying off the vessels and separating the tumor; and it was well that it had been spared, for its relation with the iliac vessels and with the broad ligament in the region of the bladder showed that it was the ureter.

On the left, near the iliac vessels, where the ureter should be situated, was found the cut extremity of a large vessel which had already been ligated. This was close to the ligature which had tied the ovarian artery, but it was also close to the iliac vessels, the peritoneum, which before had been pulled up, now having retracted. Convinced that this vessel was the ureter, I took off the ligature, and after some search found the corresponding end; and then came the question what to do. I knew of no instance where a ureter had been severed and united. Simon, on cutting a ureter, had gone on and extirpated the kidney; and Greigg Smith advises this procedure. The patient's condition, however, would not permit of such a course at that time; and the choice offered was between bringing the upper end of the ureter out through the wound, leaving the extirpation of the kidney as a future operation, or suturing the two ends of the ureter together, hoping for union if possible, but providing for leakage if it should occur. The latter course seemed preferable, for I saw no reason why a ureter should not unite as well as an intestine if properly brought together, and I had had some experience which led me to believe that the ureter had more capacity for closing a partial defect than is commonly supposed. I therefore sewed the two ends of the ureter together with two silk and one catgut sutures. I was afraid to put in more, not being absolutely sure that the distal cut end was really ureter, and also fearing that more stitches would obstruct the lumen. I therefore used the catgut, to hold if possible, and give way if necessary.

All this seems long to describe; but the decision had to be made in a minute or less, and the suturing did not take long. After thorough irrigation of the abdominal cavity, I laid the ureter where I thought it belonged, and pressed it against the floor of the pelvis on the left with the middle of a square of iodoform gauze, into which I packed strips of the same material after the manner of Miculicz. The cavity in the right side of the pelvis was similarly packed with gauze, and a glass tube carried to the bottom of the pouch of Douglas. The stump was fastened in the angle of the abdominal incision as usual, and the tube and gauze were brought out of an opening separated from the stump by two sutures.

* Read before the Obstetrical Section of the Suffolk District Medical Society.

I now felt sure that if the severed ureter should leak I could lead the urine to the surface without danger to the abdominal cavity; and my plan, if all the urine from that ureter came through the wound, was to turn the current through the lumen of the cervical canal into the vagina, and then later turn the extremity of the cervix uteri into the bladder, and so finally lead the urine where it belonged. Happily, this is not likely to be necessary.

The patient did very well after the operation; but on the fourth day the discharge from the gauze on the left side smelled ammoniacal. The gauze on the right side and the glass drain had meanwhile been removed. By the next day it was clear that some urine was escaping from the abdominal wound. The amount passed from the bladder had from the beginning been normal in quantity. The last of the iodoform gauze was now removed from the wound, and a rubber tube carried down to the site of the ureter. By care and some ingenuity the stump had been kept dry, and on the tenth day it was cut away. The quantity of urine escaping from the tube, which was never more than three ounces during twenty-four hours, now diminished; and the tube, which had been shortened, was taken out about the fourteenth day, the whole wound treated with balsam of Peru and covered with gauze and absorbent cotton.

The patient is now sitting up, and wets one napkin over the wound during the day and one during the night. I have taken care to preserve the patency of the cervical canal, and have closed in the skin so that the opening of the urethral fistula is close to the upper end of the cervical canal. The discharge is slight, however, and I hope it will finally cease without further operation.

NOTE. — November, 1893, the patient wrote that the fistula had closed entirely, that she was in perfect health and able to take active exercise of all kinds.

Medical Progress.

RECENT PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D.
(Concluded from No. 1, page 11.)

SPASMODIC TORTICOLLIS.¹⁴

HOFFA has collected the recent literature on this subject, and reports the opinions of the different writers. Paralysis of the sterno-cleido mastoid follows the operation of section of the spinal accessory nerve. Cure of the spasm does not usually follow immediately after the operation, as slight spasm of the other muscles follows, but these secondary spasms gradually diminish and in time entirely disappear. If this is not the case, Keen advises the section of the posterior branch of the cervical nerves. A head support is needed for several months after the operation, and the employment of massage is advised.

SCIATIC SCIOLIOSIS.¹⁵

Fischer and Schouwald give observations on seventeen cases, and describe the two forms which occur; the one, the homologous form in which the concavity, and the other, the heterologous, in which the convexity is toward the affected side. The former is caused

by a condition of irritation produced through the short anterior branches of the lumbar plexus, and when there is no implication of the lumbo-sacral muscle. The second type is caused by a weakness of the sacro-lumbar muscle which is due to affection of the posterior branches of the plexus supplying it. When both groups of nerves are affected, either variety is assumed, the one or the other predominating according to whether the disease affects one or the other to a greater or less degree. The second form may develop rapidly in those cases where the anterior branches either are not affected or only to a light degree, and it may also develop when the pain becomes located in this region, in those cases which appear early as the first variety. When both sets of nerves are affected to the same degree, the patient attempts to assume whichever attitude gives most ease, and the form may not then be well marked, but if improvement occurs in one or the other groups, the variety then becomes well defined.

In general, it can be said that the irritation of the anterior branches causes the homologous variety when the lumbo-sacro muscle is not affected. The heterologous variety occurs when this muscle is weak.

The following differential diagnosis is given: In the second, the patient complains of fatigue in the back, before the onset of the disease, during extension of the spine, while this symptom is wanting in the homologous form. Also the heterologous form is prolonged beyond the period of pain, on account of the weakness of the sacro-lumbar muscles, whereas the homologous disappears with the pain. The heterologous form never changes to the homologous, while the reverse often occurs suddenly. Both varieties have, however, one symptom in common, namely, that of the forward inclination of the trunk. In the second variety it is due to the action of the sacro-lumbar muscles; in the former, to a relaxed condition of the muscles supplied by the anterior branches of the lumbar plexus.

Other references to this subject may be found, by Higiea and by Remak.¹⁶

HOFFA'S OPERATION FOR CONGENITAL DISLOCATION OF THE HIP-JOINT.¹⁷

Denucé, of Bordeaux, reports a case in a child of six, operated upon by him. The child entered the hospital September, 1891, with characteristic deformity of the hip. The left trochanter major was three centimetres above the Nélaton line, while the right was upon that line. According to the statement of the parents, the shortening had increased.

An incision was made seven centimetres long, parallel to the axis of the femur, reaching four centimetres above the top and three centimetres below. The muscles were divided in the course of the fibres of the gluteus maximus, the capsule laid bare and incised. The insertion of the muscles on the great trochanter was then divided with scissors. The head of the femur was found to be slightly flattened and oval in shape; some granulations were present at the point of the insertion of the round ligament, which was entirely wanting.

If traction was made upon the foot the head could be pulled down somewhat, but not sufficiently to place it in the cotyloid cavity. The muscular insertion of the pyramidalis, the obturator internus and the gemelli were pushed backwards, and a portion of the cartilage

¹⁴ Zeitschrift für Orthopädie Surgery, 1892, p. 315.
¹⁵ Wiener med. Woch., 1893, Nos. 16 and 21.

¹⁶ Deutsch. med. Woch., 1892, 27.

¹⁷ Revue d'Orthopédie, p. 106, 1893.

of the great trochanter was cut at the point of muscular insertions. After this, the head of the femur could, under traction, be pulled downward. The cotyloid cavity was found to be small and of a triangular shape. The loose tissue in the cotyloid cavity was incised to the bone, and a flap detached with the periosteal elevator (curved on the flat), leaving the upper portion undivided and attached. This flap was raised by means of a silk suture passed through the edge, and the head of the femur was reduced underneath this cartilaginous flap into the cavity. The cavity was deepened by means of a gouge, and after the operation it was found that the head did not have any tendency to slip out of its new position. The capsules and flaps were sewn together. A traction by weight of four pounds was applied. The muscles, cartilages and the capsules were sewed with catgut, and a slight orifice left for drainage. The skin was sutured by silk. Iodoform gauze dressing. Plaster-of-Paris bandage was applied.

The temperature was raised the night following the operation and on the following day, but afterwards dropped. The patient was allowed to walk on the 30th of October, and it was found that the lordosis had entirely disappeared. The 15th of November the patient was again seen, and was found to walk well. The patient was allowed to walk without crutches on the 10th of November, and when seen a year after the operation, the patient was in good condition. There was no lordosis, and but little scoliosis; the muscular atrophy had diminished; the head of the great trochanter was not above the Nélaton line. The difference in the length of the legs was about two centimetres, having been five centimetres before.

Lorenz²⁰ reports an operation on a child of seven, and does not agree with Hoffa in thinking that the contraction of the muscles is the chief hinderance to the reduction of the dislocated head, but the muscles which arise from the tuberosity of the ischium; that is the adductive group. He considers that the reduction can be facilitated by myotomy of these muscles, and that the joint should be opened from the front, and reports four cases operated upon in this way. In one, a child of about five years of age, the reposition took place without opening the joint. One of these patients was fifteen years of age.

Karewski²¹ disagrees with both Hoffa and Lorenz, and thinks the difficulty in reduction lies chiefly in the head of the femur and in the improper shape of the acetabulum. He reports five cases. In most of the cases the head remained after operation in the new socket. An equality of length of both limbs was not gained, through the faulty formation of the neck. The good results were obtained by the use of appliances carried out for a long time. In two cases, where the apparatus was worn only three months, the head was dislocated upward again. In two, where the treatment was thoroughly carried out, the gait was almost normal.

Karewski enlarges the acetabulum by means of a chisel, dividing the cartilaginous tissue over it to make a place for the head. In a few instances he has driven a nail into the ridge of the acetabulum, keeping it there for six or eight days.

Hoffa, in the same publication, replies to both these surgeons, and states that he has operated in 24 cases, and that the definite results will be published. He

prefers an early operation, and claims satisfactory results. He does not think that the resistance of the adductor muscles is of importance, or that in all cases there is a faulty shape of the head of the femur to an extent of preventing reduction.

Nota,²² of Turin, has operated by the method of Paci upon 12 cases, of which five were double and seven were single; that is, he has operated eighteen times, eleven with good, one with partial, four with negative, and two with doubtful results. He thinks that a cause of the difficulty of a permanent cure of the deformity sometimes lies in the faulty shape of the pelvis, which is either too flat or too oblique, and that, combined with a shallow acetabulum and a rudimentary edge, promotes dislocation after reduction of the deformity. Nota regards an apparatus as necessary after the operation, and thinks that good results are largely due to this. He regards it necessary to retain the limb after the forcible reduction (the method of Paci) in a position of extreme forcible rotation outwards.

Panzeri is not convinced of the value of the method of Paci, as he does not see how the development of a new joint can be brought about simply by violent reduction.

Oliva is of the same opinion, and mentions a case in a girl of twelve operated on by him according to Hoffa's method without positive benefit, though he favors this operation in young children.

Panzeri prefers the operation of Hoffa in children from three to fourteen; in old cases the results are not good. Under three, he would advise the method of Paci and mechanical treatment.

SCOLIOSIS.

Wisser²³ has investigated the deviations of the spinal column in 515 school-children. These children were from seven to eleven years of age: 292 boys and 293 girls. Tables are given to illustrate the observations. At the beginning of the school-year a large percentage of habitual curvatures were discovered; some of them of the typical form, others of various curves. He also found that a larger percentage of curves was found in the boys than in the girls at the age of seven. The percentage of curves he found to be 41 per cent. of the boys at the end of the first school-year, and 33 per cent. of the girls. The second and third year the number had increased from 40 to 49 per cent. The increase in pathological cases was not in proportion to the longer course of study, and for that reason he concludes that the school is only one of the factors in the development of scoliosis.

Redard²⁴ calls attention to the connection between scoliosis and flat-foot. He finds this common in primary lumbar scoliosis on the side of the convexity where the lumbar curve exists.

Heusner²⁵ considers that there is a definite relationship between flat-foot and deformity of the lower extremities and the existence of scoliosis, and further claims that the element of rickets is an active one, not in children alone, but during the period of adolescence. He gives a series of observations from which his deductions are made, having examined 1,000 patients at Barmen, of whom 335 had scoliosis; 283 of these

²⁴ Gazette Medical de Paris, August 6, 1892.

²⁵ Compte rendu du 21 Congrès de Chirurgie Allemand, 1892.

showed a flat-foot. Of 663 men, 288 had scoliosis; of 837 women, 147. Of the 283 patients having flat-foot, 167 had scoliosis; and of 717 patients without flat-foot, only one-fifth showed deformity of the back. He also examined 250 infants at the orphanage, and found among these 64 with the back deformity, and 65 with flat-feet. Of the 65 cases of flat-foot, there were 24 which showed back deformity; and of 185 children without flat-foot, there were only 40 who showed a lateral curvature. Of 143 boys, 26, and of 107 girls, 28, showed a lateral curvature.

He considers that the treatment by muscular exercise to be of paramount importance, and useful in all cases; but, in addition to this, he employs the treatment of correction by mechanical force, and for this uses an apparatus which he describes and pictures in his book. This consists of an inclined plane, on which the patient rests, at the same time having head-suspension, and by means of broad leather straps weighted by sand-bags, pressure is made on the curves in the direction of correction, and this carried out for an hour or two every day. While in the apparatus efforts are made at forcible inspiration.

Schede²⁵ describes his apparatus for forcible correction. Schulthess comments upon this, and states that he has seen better correction by means of this appliance than by that of Lorenz. Schede reports excellent results, and mentions the almost entire disappearance of projection of the ribs in a sixteen-year-old child under the use of this appliance.

Messner²⁶ reports in the case of a twelve-year-old child a year after infantile paralysis the development of a paralytic curve, although the muscular paralysis had apparently passed away. The appearance was exactly as if the right side of the thorax had been imperfectly developed, and this seems to be proved by measurement. The difference between this and the ordinary scoliosis lay in the less amount of rotation. The treatment consisted in massage and electricity.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. OBSTETRICAL SECTION.

G. H. WASHBURN, M.D., SECRETARY.

REGULAR meeting Wednesday, February 22, 1893,
DR. F. H. DAVENPORT in the chair.

DR. JOSEPH PRICE, of Philadelphia, read a paper
on

OBSTETRICAL ASEPSIS.¹

DR. EMMA L. CALL: The lying-in department of the New England Hospital was established in November, 1862, and from that time till October 1, 1892, 8,259 patients have been delivered there.

In order to mark the progress of modern methods, in its effects on the health of maternity patients, it will be convenient to divide the work done into three periods of ten years each.

During the first ten years, namely, from 1862 to 1872, the hospital consisted of three small houses on Pleasant Street. The wards were necessarily crowded and inconvenient and the general surroundings not of

the best. At this time the hospital was the only lying-in hospital in Boston, and consequently received in emergencies many patients brought by the police from the worst parts of the city. The use of the clinical thermometer was quite unknown, so that we did not have the aid of that valuable danger-signal, while the employment of antiseptics in the modern sense of the word was not understood.

During this period 1,009 women were delivered, with a mortality from septic diseases of twenty, or about one case in fifty. These fatal cases occurred chiefly in two epidemics, one in 1867, the other in 1872. In addition to the twenty fatal cases there were, of course, a still larger number of septic cases, which after varied periods of illness, escaped with their lives.

In 1872 the hospital was removed to Roxbury, and a new cottage was built especially for the maternity cases. Temperature records were kept, and very early in this period, the use of carbolic acid for hands and in douches was begun. During the latter part of the period, frequent douches with carbolic acid, permanganate of potash, phenol, etc., were a part of the routine treatment of every case.

From 1872 to 1882 the number of cases was 1,026, with nine deaths, the mortality being reduced to one in 114. Nevertheless the records give us nearly every year cases of sepsis that were only pulled through with anxious care. There was no decided epidemic during this period, which was probably due largely to the fact that in 1879, an annex cottage was added, to which septic cases were at once removed and cared for by separate doctors and nurses.

In 1882 the maternity cottage was closed and thoroughly repaired and replumbed, since which time the records have been much more satisfactory.

From October, 1882 to October, 1892, among 1,224 cases (200 more than the other periods) we have lost but two patients from septic diseases, reducing our mortality to one in 612. These two deaths occurred in 1884, since which time we have had 897 cases without a death.

In the latter part of 1886 the use of antiseptic pads and of bichloride solutions for personal disinfection was established, and has been continued, with slight modifications, ever since. Patients receive an antiseptic vaginal douche at the beginning and end of every labor, and an intra-uterine douche after complicated labor. After labor the antiseptic pads, with irrigation of the external genitals before and after each urination, and rigid disinfection of the hands of the attendants before and after touching each case, is practised. If fetid lochia appear, bichloride vaginal douches are ordered; if this is accompanied by chill or decided rise of temperature, an intra-uterine douche is given. If the symptoms do not quickly subside, curettement of the internal surface of the uterus is employed.

Since this method of treatment has been followed, the number of cases which we have been obliged to isolate has steadily diminished. Most of these cases have occurred among patients who have come to us in depressed conditions of health, and their removal to the annex has stopped the trouble. Thus, during the last three years, we have had one case of septic peritonitis, and two of extensive diphtheritic deposit, occurring in different years. Not the slightest trouble among the other cases resulted from these.

In the spring of 1892 we again removed to our new

¹ See page 32 of the Journal.

²⁵ Deutsche Med. d'Orthopédie, No. 12.

²⁶ Centralbl. Chirurgie, 1892, No. 44, p. 97.

"Sewall Maternity," which has been fitted up with all the latest sanitary appliances, and where we hope the next ten years will give us still better records, than those of the past.

DR. J. G. BLAKE: I have listened with pleasure to Dr. Price's paper. During the twenty years preceding the last ten I had a large number of cases of labor, and during that time there was but little attention paid to antiseptics. I must say that I was singularly fortunate, however, and had but a small mortality. The great benefit resulting from it has been conclusively demonstrated by the results in the Lying-in Hospital. I think that favorable as they have been in the New England Hospital those of the Boston Lying-in Hospital are even better. We all remember the paper of Dr. Richardson in which he showed that in one thousand births they had had no death; and that, in fact, any rise of temperature more than one or two degrees was of rare occurrence. Unfortunately, in private practice the necessity for antiseptics does not seem to be recognized. This was brought forcibly to my attention in the uterine ward of the City Hospital, where during the last summer term of service I was called upon to curette eight or nine cases where patients had had chill, and offensive lochia and all the conditions pointing to septic poisoning. Under the treatment which we all recognize now, and which it is not necessary to speak of in detail, I believe we had no death. One woman came in in a condition which precluded recovery. If it could be made a legal obligation that doctors and midwives should be compelled to fully carry out antiseptic precautions, I think a great many lives would be saved to the community. Of course, amongst a certain class of physicians such measures are taken, and the mortality has steadily diminished; but unfortunately a large number do not fully appreciate the necessity. I believe I took that side of the question myself in the Obstetrical Society some years ago. I argued that you had susceptibilities on the part of patients, and you could not avoid septic poisoning. Dr. Richardson's paper cleared my mind of that cant; and I am a strong and earnest believer in the absolute safety attending it. If I had my way, I should make it a criminal offence if complete antiseptic precautions were not always taken.

I want to thank Dr. Price for myself and for those who were present at the operation at St. Elizabeth's Hospital this morning, for the careful, painstaking, minute carrying out of all the details of what to me was the most perfect operation I ever saw.

DR. PRICE: Boston has done more, perhaps, than any educational centre in our country for saving women. The work of Dr. Richardson and a few others cannot be estimated. It would be difficult also to estimate that great contribution of Dr. Homans. Hundreds and thousands of lives have been saved by it. I want to suggest that you read more papers. I find the profession ignorant regarding the simple precautions of cleanliness. In saying this I am not criticising Boston or Massachusetts in particular.

I am glad to hear the results in the New England Hospital. Two deaths in twelve hundred cases is hard to beat. If that means two deaths from septic cases it probably can be beaten.

The history of maternity hospitals, mixed and special, is exceedingly interesting. The mortality has varied from one to forty per cent. Several maternity hospitals have been closed. A satisfactory solution

of the shocking mortality in some hospitals can be reached when we look into matters a little. For instance, in one hospital a large sponge was used for months and years sponging patients off after delivery. This indicates that gross carelessness and reprehensible filth existed in many maternity hospitals. Some of the old nurses washed their hands superficially once a day. The towel was washed perhaps once a week. In the mixed hospitals the resident physician attended to a patient with erysipelas, and went without washing the hands to attend to a woman in labor.

I have always felt, and still feel, that maternity hospitals should be used wisely for educational purposes. The rich have to take care of the poor, and I feel that the pauper element of society should be wisely and humanely used for educational purposes, that we may have more finished physicians and more good work, and we will not attain that acme of perfection in any specialty until we have that condition of affairs, until directors and trustees realize the importance of practical education in every public institution, and until all material of that class be used wisely and humanely for educational purposes.

Dr. Price then spoke of the details of the work in the out-patient department of the maternity hospital with which he was connected. Out of eight hundred cases a year attended by the students among the poor of the city, there were sometimes one or two genuine cases of child-bed fever. Usually these cases could be traced to some neglect of cleanliness on the part of the student. In some instances scrupulously clean men had attended women in labor after caring for surgical cases, and without mischief. He had himself attended women in labor after treating all sorts of contagious diseases, and had never seen any harm arise from it. He saw no danger in this, provided a man kept himself scrupulously clean.

At the Retreat in Philadelphia patients were admitted two weeks before labor, and remained four weeks after. This he considered very important. The plumbing was entirely out of the building, which was also a very important matter, and the effect of which could be seen in the temperature charts. Patients, upon being admitted, received a thorough bath, were given a laxative, and, if there was a suspicion of renal trouble, the urine was examined. The patients receive two soap-baths weekly; the bowels are kept open; and they improve wonderfully in general health. The patients admitted two weeks before labor always do better than those admitted in labor. When a patient complains of labor pains, she receives a bath and a vaginal douche of corrosive (1 to 2,000), and goes into the clean delivery room. The toilet is made by a nurse who has nothing to do with puerperal wards. Both nurse and physician bathe before entering the room, and scrub again after entering. But one examination is made, if everything is favorable, until the head is ready to clear the perineum, when the physician sits down and superintends the delivery. After the delivery a vaginal douche is given, and the patient receives the occlusion dressing of Dr. Richardson. Nothing short of extravagance in maternity work will give a *nil* mortality. In the Retreat, out of 1,200 cases, there has been no death from any cause.

"I regard vaginal douches important, particularly in women with a relaxed vaginal outlet, in order to protect the child's eyes against acrid and irritating discharges; and if specific virus lurks there, it is the

more important that we should protect the eyes of the infant. If every woman in Massachusetts should receive in the next ten years the antepartum douche, and receive the same toilet as at the Retreat, you would reduce your blind asylums from five to one in the next ten years. All dirty instruments, and the old dirty bag which has been carried ten or fifteen years, should be discarded."

DR. E. W. CUSHING described

A CASE OF UTERINE TUMOR.²

DR. PRICE: This subject of hysterectomy I have been much interested in. I almost feel like apologizing now for a big tumor. This operation has been criticised considerably lately, and I want to say in all fairness to the operation that I know none giving me at least better results. I consider the early removal of the appendages in disease one of the most valuable operations in surgery. After the tumor grows large it becomes a very formidable operation. The size of the tumor impairs the health of the patient by interfering with breathing and by producing pressure symptoms. These growths seem to be on the increase. More of them grow now after the menopause than years ago. I have two or three patients now who have waited for the menopause, and have had the benefit of well-directed palliative treatment; and these growths have continued to grow, notwithstanding the menses ceased four or six years ago. I have removed a good number of these tumors between the ages of fifty and sixty; and the oedematous form, the muscular form and the multinodular form seem to grow more after the menopause than they did years ago. That has been the observation of a good number of operators at home and abroad. A few years ago but little was said about the soft variety of myomas. At present about every operator has something to say about the oedematous forms. They grow rapidly, they are quite symmetrical, and, as a rule, very easy to deal with. It is a quick operation.

Dr. Cushing has alluded to injuries of the ureter. I believe Keith severed one or both in one case. Mr. Tait opened the bladder in a hysterectomy he did in Albany. The bladder injuries, if the patient lives, always close; but the ureters do not close so kindly, and they are hard to manage. I have had injuries of the ureters in two cases out of 101 supravaginal hysterectomies. Dr. Cushing has called attention to the method of dealing with these capsules. Until one learns how to make a pedicle, he had better keep his hands off of them. It is of vital importance first to learn how to make a pedicle; and if you cannot make pedicles, you cannot deal with them successfully; you are apt to include bladder or something in the pedicle. I am satisfied from my own experience that you should never use a temporary clamp, that you should simply use a large, long-bladed, hæmostatic forceps, and never a constrictor before severing this great capsule. I am satisfied that many of the early operators included one or both ureters in the pedicle, and that to that may be attributed some of the deaths from so-called suppression, etc.

DR. H. W. CUSHING showed two tubes and ovaries removed on account of inflammatory trouble. The tube on the left side was largely dilated, and there was an abscess situated apparently in the left ovary. This communicated with the vagina and with the rectum.

² See page 37 of the Journal.

It was removed by enucleation, breaking up adhesions, ligating and cutting off. Two small fibroids were also taken from the uterus of the same patient.

DR. E. W. CUSHING showed specimens of pus tubes.

DR. PRICE: Our present idea of the pathology of pelvic inflammatory troubles has been slow in gaining ground. In New York I do not believe they have as yet accepted it. It would seem from what they are doing at present that every woman suffers from endometritis, that every patient must be curetted. Now, in the presence of those huge abscesses, of course, the woman has a discharge. In this case the woman did discharge from the bladder and bowel. Why not curette the bladder? The indications are as clear as for curetting the uterus, and yet that goes on for this condition of affairs in New York. There is but one treatment in these cases. As yet I have never found a pelvic abscess wholly independent of ovarian disease except in traumatism or criminal abortion. A good number of these cases are treated for typhoid fever, appendicitis, dysentery, etc. They are not examined. There has been of late a good deal of conservative talk and writing; but as this conservative talk goes on, the complications increase and our cases are getting worse. They are neglected. All this talk means a higher mortality for all of us.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON ORTHOPÆDIC SURGERY.

STATED Meeting, October 20, 1893, W. R. TOWNSEND, M.D., Chairman.

A CASE OF CLUB-HAND AND CLUB-FOOT.

DR. REGINALD H. SAYRE presented a little boy with a congenital club-hand. There was an absence of the thumb, radius, and certain of the carpal bones, and also a marked curve in the ulna. This last was corrected by subcutaneous osteotomy. Some weeks later, an open incision was made, and it was found that the ulna did not articulate with the carpus, and that there were some ligamentous bands which bound down the hand at right-angles to the forearm. These bands were divided, and an attempt made to bring the hand down, but the flexor tendons, particularly the flexor carpi radialis, were so short that it was not practicable to bring the styloid process clear of the carpus. He then removed the os magnum and the unciform, cut off the styloid process of the ulna, and put the bone into the cavity thus formed. Another time he would not destroy the ligaments on the posterior part of the carpus, on account of the difficulty experienced in keeping the bone in place. There is still a noticeable tendency for the hand to turn to one side, as there is a very small surface on the ulna out of which to make a wrist-joint.

He had seen a picture of a similar case where the carpus articulated with a facet on the side of the ulna, making a good joint. Under such circumstances, one might cut the ulna just above the articular surface, and turn it at right-angles to itself, thus bringing the joint surface in its normal position.

His patient also had a congenital club-foot, which was operated upon before the hand was treated, by the use of subcutaneous incisions and Bradford's instrument. This boy also had a curvature of the spine, and the right upper and lower extremities

seemed to be more developed than those on the other side. Since the deformity of the foot had been corrected, there had been a notable improvement in the lateral curvature.

The speaker said he had only seen five cases of club-hand. In one case under treatment at present, an infant of three or four months, plaster-of-Paris dressings are applied, and changed at short intervals; and he expected a fair result. In the other cases there were simply contractions of the tendons, but the skeleton was apparently normal.

A CASE OF MYOSITIS OSSIFICANS, WITH MULTIPLE EXOSTOSES.

DR. V. P. GIBNEY presented a boy, ten years of age, who was admitted to the Hospital for Ruptured and Crippled for the first time when five years old. At that time a diagnosis was made of myositis ossificans affecting the levator anguli scapulae. He was taken into the hospital with the idea of severing the strip of ossified muscle, but the parents would not consent to the operation, and removed the child. He did not return until last spring, when he was seen by Dr. Townsend. He stands with his head tilted a little to the right; the upper extremities are bowed so that the thumbs touch, and the elbows are separated some distance from the sides. There is a bony enlargement springing from the middle of the jaw, about the size of a split pea. He is able to bring his neck up to a vertical bearing, but his head soon falls down into the position already noted. The rotation of the head is limited to a very small arc, about ten degrees. The right clavicle has an extra curve at its outer half, the greatest convexity being toward the spinal column. The outer end presents an appreciable enlargement, while the sternal end is subluxated forward and seems to be ankylosed. The left clavicle presents an unusual curve throughout its whole extent, the convexity being towards the neck. Springing from the middle is a bony, irregular mass, elevated half an inch. The base of the tumor spreads out into the clavicular portion of the pectoralis major, and continues into the pectoral portion, terminating in an irregular mass in the anterior wall of the axillary space, deepening this space very much. Over the articular surface of the second rib with the sternum is a small exostosis, which shades off into the mass just mentioned. There are similar exostoses over the sternal end of the third and fifth ribs. There are no such bony masses on the right side. The respiratory movements of the thorax are limited. Beginning about the middle of the fifth rib, just in front of the axilla, is a bony enlargement, triangular in shape, which extends backward and downward, taking in the whole area of the latissimus dorsi and the serratus magnus. He was re-admitted to the hospital on March 9, 1898. With the idea of freeing the shoulder, the bony tendon of the latissimus dorsi on the right side was divided, and a piece of bone about one inch wide and very dense and hard was excised, but new bone was thrown out very soon, and the mass became if anything more unyielding than before. There was also a peculiar osseous tumor over the right tendo-Achillis, about the size of a peanut, which interfered with his wearing a shoe. This was dissected out at the time of the other operation, and has not recurred.

About the time of this operation an old case returned which he presented to the Pathological Society many

years ago. An account of it was published in the *New York Medical Record*, 1875, Vol. X, page 747. She was at that time ten years of age, and first came under his care on September 14, 1875. She had been perfectly well up to December, 1874, when she had an attack of diphtheria, followed by paralysis of the vocal cords. The muscles involved in her case were the latissimus dorsi, the scaleni, and the erector spinae. Her right arm was held down by the tendon of the latissimus dorsi, and she suffered more or less pain in her back. There was also a lateral curvature from lack of muscular tone. At the suggestion of some members of the Pathological Society, she was put on lactic acid; and though no real improvement was noted, it was observed that after a year and a half there had been no further increase in the disease. Since 1884 she has been working at millinery, and the disease has made no further progress.

The boy just presented has been taking lactic acid for the past six months. He has had very little pain.

The speaker said that so far as he had been able to ascertain, the first American case of this kind was published by Dr. Byers in the *New Orleans Journal of Medicine* in 1870. The first reference to the subject which he had found in literature was by Bulhak, who published a dissertation on the subject in 1860. Kummell has reported a case where the ossification probably began in intra-uterine life, since it was noticed as early as fourteen days after birth. When the child was two years of age, there were numerous fluctuating tumors over the back, which ultimately became as hard as bone. Nothing is known of the etiology. There is no traumatic element in the case presented by him.

DR. N. M. SHAFFER said that such cases must be very rare, as this was the first of the kind he had ever seen. He would suggest that the electrical reactions of all the muscles be determined, also the condition of the reflexes, and that a critical examination be made of all the organs. He would classify it as a nervous disease, the changes in the muscles being the result of pathological changes in the central nervous spinal system.

THE TREATMENT OF CLUB-FOOT BY WOLFF'S METHOD.

DR. A. B. SHANDS read a paper on this subject, exhibited a number of illustrative cases, and gave a demonstration of the manner of carrying out the treatment.

DR. SHAFFER asked how many of the patients had been operated upon prior to the adoption of Wolff's treatment.

DR. SHANDS replied that most of them had been operated on previously, but in one of the cases exhibited no operative treatment had been employed.

DR. SHAFFER said that the principle embodied in this treatment was one which he had taught for a long time. By this method one accomplishes with plaster-of-Paris what he had long done, and he thought in a more thorough manner, with his lateral traction shoe. With lateral traction a certain amount of force is applied at frequent intervals. His success had been such as to entirely warrant him in saying that the method just presented is perfectly competent to bring about a cure, and hence, it would be found very useful where more elaborate apparatus is not obtainable. He preferred to make changes in the position of the foot every three or four hours instead of at intervals of a few days, as in the method described in the paper.

The great majority of cases of club-foot under ten years of age can be cured without operative interference.

DR. HENRY LING TAYLOR said he had been much interested in Dr. Freiberg's account of Wolff's method when published in the *Medical News*, for the method seemed very reasonable, and presented certain analogies to one which he himself employed. The method described in the paper was simple and efficient, and placed the proper mechanical treatment of club-foot within the reach of any country practitioner who possessed a clear notion of just what he wished to accomplish.

Last summer while away from the city, he had seen, at the request of a surgical friend, an easily curable case of club-foot in a child two years old. Nothing had been done because the surgeon was "waiting until the child was old enough for an operation." This was a great mistake; if the surgeon cannot construct a proper splint out of metal or wood, he should correct the deformity by means of plaster-of-Paris dressing, according to the method shown this evening. There was not much difference between this method with plaster and that which he had called "the method of continuous leverage." In the former, moderate correction is made, and the foot retained in this position. The correction goes on while the splint is applied, because the foot continues to yield; when it has yielded sufficiently, another correction is made in the splint. This is not very different from applying his leverage apparatus, and following up improvement in the position of the foot by adjusting the straps or bending the side-bar from time to time. The foot is being continuously impelled in the right direction, and is at all times prevented from falling back into a wrong position. This method of Wolff is essentially the same in principle.

DR. A. B. JUDSON said that in children as young as these, the deformity easily yields to persistent and appropriate treatment. Plaster-of-Paris used in this way embodies a lever with points of pressure and counter-pressure; but he preferred to use steel, adhesive plaster and webbing, by which more gradual steps are made toward correction, taking more time, giving no pain, and taking advantage of the weight of the body properly directed on the foot, the same apparatus being used for the after-treatment as long as may be required. He was reminded by Wolff's method of having seen Dr. Gibney many years ago using plaster-of-Paris and a wedge in the reduction of flexion of the knee. He was surprised that there are so many young children whose club-feet are neglected till large calluses form on the outer borders of the feet. Our duty is to extend a knowledge of what may be done with little trouble on the part of the family physician towards correcting this deformity in young children.

Recent Literature.

Manual of Bacteriology for Practitioners and Students, with especial reference to practical methods. By DR. S. L. SCHENK, Professor Extraordinary in the University of Vienna. Translated from the German (by the author's permission) with an appendix by W. R. DAWSON, B.A., M.D., Univ. Dubl., Late University Travelling Prizeman in Medicine. With 100 illustrations, partly colored; 302 pp. with an index. London and New York: Longmans, Green & Co., 1893.

The book appropriately begins with an introductory chapter on the general morphology of micro-organisms, after which bacteriological technique is considered. Then follow chapters on the bacteriological analysis of air, water, foods, putrefying substances and pus. In the remaining chapters the organs and cavities of the body and their contents are discussed from the point of view of bacteriology. Under these various heads, descriptions of the bacteria met with are given, an arrangement of the subject which is quite satisfactory.

The bacteriological methods are, on the whole, well described, though there is much that is disappointing.

A great many staining methods are included, some of which are certainly rarely used and are of no importance. It would seem that in a book of the scope of this one a much smaller number of well-approved methods, selected with the discrimination of a trained bacteriologist, would better suit the needs of those for whom the author writes. We note with pleasure that the use of the double glass dishes of Petrie is recommended for obtaining discrete colonies, though the antiquated and cumbersome apparatus of Koch is still described with great detail and illustrated by figures, some of which have grown familiar in other books on bacteriology.

In the chapter on air we find no mention of the excellent method of Sedgwick. The description of the biology of the various species of bacteria is, in general, unsatisfactory. Numerous saprophytes which are to be found in all of the text-books on systematic bacteriology here also appear, but the customary descriptions of most of them, useless and inadequate as they are for purposes of their identification, have been still further abbreviated by the author, so that it would probably be just as well if he had limited himself to a simple catalogue of their names. In the treatment of the pathogenic and better studied bacteria, similar defects are observed. A conspicuous instance of this is seen in the case of the typhoid organism, the differentiation of which from the bacillus coli communis, is very imperfectly given; some of the most important and trustworthy distinguishing characteristics being altogether omitted. The statement is also made that the typhoid bacillus forms spores and the same is said of the bacillus prodigiosus. This teaching is not now accepted. The account of the relations of various bacteria to pathological conditions of the organs and tissues of the body is also defective. Thus little or no importance is assigned to the part played by the streptococcus in pseudo-membranous inflammation of the throat.

The translation is done in a very readable manner, but here and there an apparent ignorance of the technical English equivalents betrays itself by the use of the terms "islets" for "colonies," "thrust" for "stale" culture, Petrie's "capsules" for Petrie's "dishes" or "plates," "second" for "secondary" infection, "heat" for "temperature." At times also there are indications of a too close adherence to German idiom.

In an appendix by the translator there are *résumés* on the subjects of pathogenic protozoa, cholera vaccination, and action of light on bacteria, together with some additional technique.

The publishers' part has been well done in Messrs. Longmans' well-known style. Some of the illustrations are new and excellent, especially those of gelatine cultures which constitute the most valuable part of the book. Many, however, are taken from the usual stock in common use. Misprints are few.

Diseases of the Skin. By H. RADCLIFFE CROCKER, M.D., (Lond.). Second edition, revised and enlarged. Philadelphia: P. Blakiston, Son & Co. 1893.

We are somewhat late in taking notice of the second edition of Dr. Crocker's work for the reason that a hasty examination convinced us that the large amount of new matter that had been added, together with the many alterations, demanded careful reading and study, and it is with great pleasure that we are able to say, that the time has been most profitably spent. As a proof that dermatology is not standing still, we may point to the fact that one of the foremost dermatologists of Great Britain, a writer who has shown much critical discernment in his attitude towards innovations, has felt justified in adding to the list of affections that appeared in the edition of 1888, twelve titles of more important affections of the skin, and thirteen subjects of minor interest. Too much praise cannot be accorded for the careful and systematic manner in which these new subjects have been presented, so that this book will be gladly turned to by the expert, as well as by the general practitioner, when a short, accurate account of the modern contributions to dermatology is demanded. Much weight and dignity is added to the book, by the impartial and scientific spirit shown towards the so-called "schools" of dermatology, and to this much of the book's value must be attributed. The writings of German, French and English speaking people have been impartially and carefully studied, and the result, as we view it, shows that no one school can to-day afford to slight the contributions of the others, without danger of retrograding.

As is natural, we are not always able to agree with the writer, but that is mostly in matters of minor details. We should have liked to see lupus vulgaris included together with scrofuloderma, and verrucous tuberculosis, under the heading of tuberculosis of the skin, and cannot but think that an abundance of material was at hand for an amplification and broader treatment of this whole subject. Dermatitis herpetiformis is treated under the heading hydra herpetiforme. It is better and fairer, we think, to retain the name given it by Duhring, who was the first to call attention to the polymorphism of this disease, until its pathology and etiology have been more clearly defined. It is gratifying to see impetigo contagiosa, ecthyma, furunculus and carbunculus grouped together under diseases due to pus cocci, and these affections are considered tersely in the light of modern pathology.

The paragraphs on pathology are well and critically written and receive added value from the author's experience in histological investigation. The treatment is more concise and emphasizes the writer's own preferences more strongly than is the rule in text-books, and this is also a merit, as a prosaic rehearsal of the different drugs that have at any time been used, is apt to prove an embarrassment rather than a help, to the seeker for aid in therapeutics.

Altogether this second edition of Crocker stands, in our opinion, as the best modern exposition of the subject of dermatology that has been offered by an English-speaking writer.

THE total income of the London Hospital Sunday collections for 1893 was £39,000 as against £41,000 for 1892.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 11, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE THERAPEUTIC ACTION OF BLOOD-SERUM.

At the present time when reference is so often made to the action of blood-serum in producing immunity, another brief *résumé* of the leading facts in connection with it, and what has been established is timely, and will be of aid in understanding the value of future experiments in the same line. Such an analysis has been recently made by Günther, and it is from his article that the chief points in our present review of this subject are taken.¹

The principle rests on the discovery of Behring, that the serum from an animal, which has been rendered artificially immune to a disease, if introduced into the body of another animal, cures him of the disease or renders him immune. Thus the mouse, which is especially susceptible to tetanus, is cured after the outbreak of the disease through the injection of the serum from a horse that has been made artificially immune.

But before sketching the development of the blood-serum therapy, the chief points of the theory of immunity must be touched upon.

It is well-known that one species of animal is very refractory to a certain infectious disease, while another is very susceptible. Among the susceptible individuals there are those which have a greater or less degree of immunity. This rests on unknown factors. These can, however, be acquired, accidentally or otherwise, through exposure to which the individual is subjected. A child which has passed through scarlet fever, is generally immune for the rest of its life, through accidental exposure to the disease. On the other hand, a sheep, very susceptible to anthrax, can acquire immunity against this through an intentional artificial vaccination.

From the time of Jenner to 1880 there was no advance made in the direction of protective inoculation. In that year Pasteur found that if the bacterium of hen cholera was exposed to the air for months its

¹ Carl. Günther: Die Blutserumtherapie. Ihre geschichtliche Entwicklung und ihr gegenwärtiger Stand. Deutsch. Med. Woch., November 16, 1893.

virulence was greatly lessened. If a hen was inoculated with one of these weakened cultures, there was set up only a local transitory affection, and after this had passed off the bird was not susceptible to the virulent form of the disease. The same line was followed in the artificial immunity given to animals through the injection of weakened cultures from anthrax, swine plague, and hog cholera. Various methods to attain this weakening of the virulence were employed. For some the action of oxygen was sufficient, to others chemical substances had to be added. Others had to be grown at a high temperature, while others had to be passed through the body of some other animal. In general, it was found that in order to be weakened, the bacteria must be placed under conditions which are unfavorable to them. As to the real cause of this, little can be said to be known. Many show no change of form or method of growth, while with others a partial degeneration goes hand-in-hand with the decline in virulence.

Several hypotheses have been advanced to explain the action of these less virulent forms and the changes in the body of their recipient.

The first, which may be called the hypothesis of "exhaustion," was supported by Klebs and Pasteur. This supposes that to produce immunity some peculiar nutritive material of the body necessary for the bacteria was used up, so that bacteria that came afterwards could not thrive. This hypothesis is to-day given up. Another which comes nearer the truth is that of "retention," advanced by Chauveau. He believes that for immunity certain products of the bacteria must be kept back in the body, and that these prevent further growth. A third is that of Metschnikoff, grounded on his theory of phagocytosis. He has shown that certain of the body-cells, especially the white corpuscles of the blood and the larger cells of the organs, have the power to seize upon and destroy bacteria. For the act of immunity it is necessary that the phagocytes should first destroy the weaker forms, and in this way they acquired the power to make way with the virulent ones.

A further advance was made by Salmon and Smith in 1887, who discovered that immunity was possible through pure chemical means. Thus the products of a culture of hog cholera, freed from all bacteria, could render pigeons immune to the disease. By this it was surely proved that it is a chemical change of the juices of the body in the act of immunity, which makes the body resistant to the attacks of the virulent bacterial material.

At about the same time Fodor showed that the juices of the normal living body, especially the blood, possessed qualities destructive to bacteria. Blood freshly drawn from a vein was found to kill large numbers of the bacteria placed in it. This property was lost after a few hours, however, and then all kinds of bacteria grow abundantly in it. Serum was found to work in the same way. And Buchner in 1889 announced that the albuminoids in blood-serum freed

from all cells were the possessors of this peculiarity. At the same time it was discovered that all serum did not work in exactly the same way. While these facts might be used in the explanation of immunity, they were found to fail in so many cases, that they had to be set aside, and the conclusions formulated as follows: "The bactericide properties of the blood or its serum cannot be used in general to account for the condition of immunity."

Further studies made in this field by Behring brought out, however, a perfectly regular peculiarity of the blood-serum of an individual rendered artificially immune. He stated this as follows, and it is called Behring's law: "If an individual is rendered artificially immune against a certain infectious disease, then his blood or its serum has acquired the property of transmitting immunity against the same infectious disease to a susceptible individual (no matter of what species) into whose organism it can be brought in sufficient quantities."

The first communication was made in regard to tetanus by Behring and Kitasato in 1890. They were able to render rabbits immune against tetanus. The blood-serum of these rabbits, when introduced into the bodies of mice (extremely susceptible to this disease by nature), protected these little animals completely.

It must be mentioned here that the tetanus bacilli belong to that group of bacteria which are called "toxic" in contradistinction to the "infectious" in the narrowest sense. These last work harmfully by their enormous increase in the body, while, on the other hand, the toxic work by the production of a specific poison. If the tetanus spores enter into a susceptible body they develop in the spot of introduction, and it is here that the active poison of tetanus is produced, which is taken up into the body, and then develops its general deleterious working. The poison can be produced outside of the body in artificial cultures as well. If such a culture is freed from its living bacteria (by filtration), then this filtrate, introduced in proper doses into the body of an animal, causes an outbreak of tetanus just as surely as if the bacteria are used. In the first case it is a tetanus infection. The bacteria penetrate the body and increase. From this there is developed an intoxication, which is absorbed from the poison produced by the developing bacteria. In the second case we have at once, and primarily, an intoxication. The ready-formed tetanus poison penetrates the body as a soluble chemical, and acts thus.

Behring and Kitasato have shown in the above work that the introduction of the serum of animals made immune against tetanus protects the susceptible animals not only against the infection of tetanus, but also against the primary intoxication. These authors have thus added a new point to our knowledge of immunity, and have drawn the following conclusion from their experiments: "The immunity of the experimented animals depends upon the capability of the blood-serum freed from cells to render harmless the toxic substances which the tetanus bacillus produces.

A further proof is that the blood-serum of animals made artificially immune acts in the same way against the tetanus poison in the test-tubes. Further, it was found that animals suffering from tetanus could be cured by the inoculation of the serum of immune animals. This acquired resistance rests, therefore, on the antitoxic peculiarities of the blood-serum."

This epoch-marking discovery in the case of tetanus has been the point of departure for a great number of experiments to see to what extent the blood-serum of artificially immune individuals can be used for the purpose of healing in the infectious diseases. As would be supposed, investigation has been carried on with the blood-serum of individuals immune by nature, and the result has been that in their blood-serum there is no substance which can render other individuals resistant. These substances are therefore never present naturally in an individual, but must be first formed; and this happens only by artificial means. For the understanding of natural immunity, every point fails us at the present time.

Diphtheria was the next disease to tetanus to be investigated (1892). We have to deal here with one which is also produced by toxic bacteria. Here all the general symptoms are to be referred to an intoxication; and the blood-serum of artificially immune individuals was proved to be active through its antitoxic properties. This process of immunization against tetanus and diphtheria can be regarded, from the nature of those diseases, in the light of a seizure of the virus (*Giftfestigung*). Ehrlich, too, has shown that Behring's law holds also for the seizure of other poisons than those produced by bacteria. He was able to render mice immune against ricin (an extremely poisonous albumen obtained from the seeds of the ricinus communis), as well as against abrim (the toxic albumen from the jequirity beans), by feeding them with gradually increasing doses of these poisons.

The serum of these animals was capable of transferring its property of seizing these poisons to healthy animals. It also rendered the poison harmless when they were brought together in the reagent glass.

In all infectious diseases Behring's law has turned out to be true, even where one cannot speak of the seizure of the virus. For example, in all cases of septicæmia which have been investigated in this regard. Even in those where as yet the poison has not been isolated—for example, rabies—it holds good that the blood-serum of artificially immune individuals can transmit immunity to normal individuals.

The above investigations have also thrown light upon the spontaneous healing of infectious diseases. This appears, in general, to come about when there have been formed in the body, especially in the blood, substances which paralyze the harmful agents. If the disease has been overcome, these "anti-agents" in the blood are found afterwards. In men who have lived through a pneumonia, typhus, cholera or diphtheria, the blood-serum has been found to act in rendering animals immune.

It has been stated above that the protective serum can also heal diseases that have already broken out (therapeutic action of blood-serum). But it has been generally found that very much more serum is necessary for healing than to produce immunity; and still more is needed the further advanced the disease. And, furthermore, the necessary amount stands in direct relation to the body-weight of the individual.

It will at once be realized that there are practical difficulties in the way of obtaining a large quantity of very active serum for treatment in the care of man. In the two diseases in which it has been tried, diphtheria and tetanus, the sheep and horse are the animals from which the immunizing serum has been obtained. The results from this treatment, however, will have to be subjected to the severest scrutiny before all that is claimed for them can be allowed. Certainly the work is a great contribution to our understanding of these obscure processes, and while that can at once be accepted, the practical outcome must still be regarded as under judgment.

Of the chemical nature of the active substance in the serum there is little known. In the case of the anti-tetanus, it has been found to be very resistant against physical, chemical and atmospheric influences. It passes through the dialyser, and by this the characteristic reactions for albumens are lost.

It has been shown by Ehrlich that the immunizing substance of the blood can pass into the milk, and through nursing immunity can be obtained. At the same time, it has been shown that immunity (through seizure of the poison) can be transmitted through the mother, but not the father. In the inheritance of artificial immunity two factors come into play: first, the supply of the foetus with immunizing substances from the maternal blood, and, second, the continued accretion to this by the offspring through the milk.

In regard to the length of time and the persistence of the artificial immunity, the two ways in which it can be acquired are to be kept sharply separated. If the immunization is "active"—that is, if the body itself helps prepare the substance which overcomes the disease—then the resulting immunity is relatively strong, and exists a long time. If, on the other hand, it is "passive"—that is, if immunity is given to the organism by the introduction of serum, blood or milk in which the agent is already prepared, then the immunity is a relatively short one, probably not extending over more than a few weeks.

MEDICAL NOTES.

THE CONGRESS FOR HYGIENE AND DEMOGRAPHY.—At the eighth International Congress for Hygiene and Demography, to be held this year at Budapest, an entirely new section is to be organized for the study of the hygiene and etiology of diseases of the tropics. Dysentery, malaria, yellow fever, elephantiasis, beriberi, the influence of tropical climates upon Europeans, tropical affections of the liver, and the effects of the

use of alcohol in warm countries, are some of the especial topics for discussion.

FIRE IN A LONDON HOSPITAL.—A fire occurred in the Royal Free Hospital in London, last week, which was extinguished with some difficulty. The patients in the wards were all removed safely, and no serious damage was done.

SMALL-POX AT NASHVILLE, TENN.—Six cases of small-pox were reported at Nashville, Tenn., January 8th, from four different sections of the city, all of the patients being negroes.

BOSTON AND NEW ENGLAND.

BOSTON WATER CONSUMPTION.—The daily average consumption of water in December last was as follows; Sudbury and Cochituate system, 47,807,800 gallons as against 43,766,400 in December, 1892; Mystic, 11,620,800 as against 10,475,700 for the corresponding month of 1892; total, 59,428,600, an increase of 5,188,500 gallons over December, 1892. The flow of the Sudbury and Cochituate is now about 10,000,000 gallons a day more than its consumption.

BEQUESTS.—The Carney Hospital and the Free Home for Consumptives of Boston, have each received a bequest of five hundred dollars by the will of Mr. Dennis Cawley.

FREE VACCINATION IN BOSTON.—The free vaccination stations were closed last Saturday evening. During the two weeks in which they were open over forty thousand persons were vaccinated. During the present week a physician is to be sent to each public school to vaccinate all children who are in need of it, though the vaccination is not to be compulsory.

SMALL-POX IN BOSTON.—There have been five new cases of small-pox in Boston in the week ending at noon January 10th. There have been no deaths.

SMALL-POX AT LOWELL.—Several new cases of small-pox have occurred at Lowell, Mass., during the week and there are now seven patients at the small-pox hospital, one of whom is not expected to live. In spite of these cases much opposition is being shown to vaccination in both Lowell and Lawrence, chiefly by the German population.

SMALL-POX AT WORCESTER.—A case of small-pox occurred at Worcester last week, in an employé at a tannery. His boarding-house has been put under close surveillance.

INFLUENZA AT PORTSMOUTH, N. H.—The influenza is prevalent to a serious extent in Portsmouth, N. H. Over seven hundred persons are now ill, and there have been many deaths during the last few days, directly due to the gripe.

"VARIOLENA."—Several cases have come to notice this week, in which patients have been given some small white, sweet-tasting pills to take every two hours or so for the purpose of "effecting vaccination without the discomfort of scarifying and causing a sore arm." In, at least, one case, the patient had been un-

successfully inoculated, and was told, "Well, no matter, the pills will do just as well."

NEW YORK.

ACADEMY OF MEDICINE ELECTIONS.—At the annual meeting of the New York Academy of Medicine, held January 4th, the following officers were elected: Vice-President, Dr. Joseph D. Bryant; Member of the Board of Trustees, Dr. Abraham Jacobi; Treasurer of the Board of Trustees, Dr. Wm. F. Cushman; Member of the Committee on Library, Dr. W. Gilman Thompson; Member of the Committee on Admissions, Dr. John S. Warren.

DEATH OF MRS. LEWIS A. SAYRE.—Much sympathy is felt in the profession and the community at large for the venerable Dr. Lewis A. Sayre, on account of the loss of his estimable wife, who died suddenly on January 5th, in the seventy-second year of her age. Mrs. Sayre was the daughter of the late Charles Henry Hall, and came of a distinguished old New York family. Up to a day or two of her death, she enjoyed good health.

THE WAY SMALL-POX IS SPREAD.—The way in which small-pox is often spread is strikingly illustrated by the discovery of three cases in a tenement-house in Harlem. On December 20th, a man by the name of Murphy was found with the disease in the annexed district beyond the Harlem River, and sent to the hospital for contagious diseases on North Brother Island. The house was promptly fumigated, and the inmates vaccinated, but the wife of the patient managed to escape the vigilance of the authorities, and disappeared with her child. On January 4th, the officers of the Bureau of Contagious Diseases found the child and two Italian children suffering from small-pox in a house on East 111th Street. In the meanwhile, the Board of Health is carrying on the work of general vaccination vigorously, and the extra corps of vaccinators, whose term expired with the old year, has been reappointed.

APPROPRIATION FOR THE BOARD OF HEALTH.—The \$425,080 mentioned in last week's JOURNAL as having been appropriated for the expenses of the Department of Charities and Correction for 1894, should have been set down to the Board of Health.

TUBERCULOSIS AMONG LEVI P. MORTON'S CATTLE.—Seventeen pure Guernsey cattle owned by ex-Vice-President Levi P. Morton, at his country place at Rhinecliff on the Hudson, have been found to be suffering with tuberculosis, and the State Board of Health, acting on the report of Dr. John Faust, of Poughkeepsie, have ordered that they be killed. Dr. Faust is of the opinion that the tubercle bacilli have only recently invaded the systems of the cattle from the fact that the animals are to all outward appearance entirely free from disease, the presence of tuberculosis having been revealed only by the Koch test of the hypodermic injection of tuberculous matter. Among the infected cattle are a number which were exhibited and won prizes at the Chicago World's Fair, and it is

probable that the disease was contracted there. It is stated that over one hundred head of cattle exhibited at the Fair from the State of New York, have been found, by the Koch test, to be suffering from tuberculosis, and have been killed.

Miscellaneous.

INAUGURAL ADDRESS OF THE GOVERNOR OF MASSACHUSETTS.

In his inaugural address, Governor Greenhalge recommended the passage of a medical practice act by the State Legislature. He said:

"I ask you also to consider the expediency of requiring that practitioners of medicine be registered, in somewhat the same manner as pharmacists are now registered.

"In every State of the Union, except five, such a system of registration has been established, and it cannot fail to protect the public, and at the same time help to maintain a high standard among medical practitioners."

Other matters of medical interest of which he spoke were the various State boards and their work.

"The work of the State Board of Lunacy and Charity is one of vast scope, comprehending the supervision and visitation of the public and private insane hospitals and asylums of the State, State almshouse and State farm, and three State schools, and the State and town almshouses containing insane inmates; the care of insane patients boarded in families, with the supervision of juvenile offenders, and the administration generally of the laws concerning the support of State paupers by cities and towns, together with many other duties of kindred nature.

"The importance to the community of this great work of charity cannot be overestimated. It is in such lines of work that Massachusetts has won her high reputation among the States of the Union and throughout the civilized world.

"The care and improvement of the unfortunate coming within the jurisdiction of this Board is no insignificant standard by which to mark and measure the degree of civilization in this community.

"The work assigned to the Board appears to have been faithfully and efficiently performed in all its departments."

After calling attention to the need of new buildings to prevent overcrowding, and the necessity of separating the different classes of inmates, the innocent from the criminal, he said:

"Various suggestions will be made by this Board in their forthcoming report in regard to amending the statutes relating to the form of mittimus, the commitment laws, the record books in the State hospitals, and on various other points which I regard as practical and beneficial. The propriety of furnishing to the insane some light and interesting employment merits also your consideration.

"The Board of Health is performing its difficult and responsible duties in a most effective and satisfactory way. The Board exercises a strong and salutary influence over local Boards of Health. The year just closed has been marked by faithful and intelligent labor, and by excellent results, as the report of the Board will plainly demonstrate.

"I commend this report, with its suggestions and recommendations, to which I find no occasion to add anything, to your careful examination."

THE DUTIES OF ARMY MEDICAL OFFICERS.

At the opening session of the newly established Army Medical School, Colonel Alden, President of the Faculty, spoke of the important duties of an army medical officer. He should be a sanitarian first and a practitioner next. His primary duty is to prevent disease and preserve the efficiency of the command. The questions of practical sanitation which he must deal with at every turn he has had but little experience in. Questions of soil, buildings and ventilation, of drainage, sewerage and disposal of garbage, the wholesomeness of water-supplies and animal foods are but a few instances of the many points bearing on the preservation of the health of the military comitia under his sanitary care, on which the ordinary medical graduate needs further instruction to fit him for military service.

"The actual duties of the medical officer are divisible into three branches. First, he is to see that none but able-bodied and effective men fit to perform the duties and endure the hardships incident to military life are admitted to the service. He must therefore critically examine the voluntary recruit or person about to receive a commission. Second, he must carefully watch over the health of the command to which he is attached in order that no causes that may mar its efficiency can gain headway. He knows that the mere aggregation of men leads to disease and that the experience of all campaigns shows that disease kills more than does the enemy. He must be ever ready to draw attention to unsanitary conditions. Third, he must keep himself always ready to relieve the sick and wounded in garrison and in the field; to endeavor to make them effective again at the earliest possible moment, or extend such measures of relief as may be possible if restoration to duty is impracticable."

DRUNKENNESS IN WASPS.

SOME of our readers may have seen a flock of crows fed on corn or meal previously saturated with whiskey, and grieved at the wickedness of man in extending the vices of civilization to the innocent animal world. They may be relieved, or perhaps even more grieved, to learn that the desire for strong drink is natural in other orders than man. Mr. Lawson Tait, in an address on the use of alcohol, relates the natural fondness of wasps for intoxication. He says:

"I have watched wasps with great interest, and have noticed the avidity with which they attack certain fruit when fully ripe, rotting, in fact, and I have also noticed some of the peculiar results of their doing so. The sugar in some fruits which are most attacked by wasps has a tendency to pass into a kind or kinds of alcohol in the ordinary process of rotting, a fact which is easily ascertained by the use of a still not large enough to attract the attention of the excise authorities. On such fruits, particularly grapes and certain plums, you will see wasps pushing and fighting in numbers much larger than can be accommodated; and you will see them get very drunk, crawl away in a semi-somnolent condition, and repose in the grass for

some time, till they get over the "bout," and then they will go at it again. It is while they are thus affected that they do their worst in stinging, both in the virulent nature of the stroke and the utterly unprovoked assaults of which they are guilty."

WORK AS A THERAPEUTIC AGENT.

A CORRESPONDENT has sent to the *Spectator* the following short letter from Sir Andrew Clark :

DEAR — : There are two things about all patients which help us to discover their maladies : what is found by the physician and what is felt by the patient. What is felt helps us very little ; what is found, for the most part settles our judgment. What is felt by Mr. — amounts to a great deal. Various disturbances of digestion, weakness, inaptitude for work, recurring faintnesses, *malaise*, and the feeling of getting worse and worse. What I found amounts to very little. . . . Every organ that I can reach is free from obvious structural disease ; and as the patient has suffered for years in this way and nothing has come of it, it is reasonable to say that there is no structural disease. Mr. —, therefore, is ailing, and perhaps suffering, but not in the ordinary sense ill ; furthermore, I think that he is introspective, morbidly nervous, and occupied with himself. He cannot at present be made well ; but he may reach his best by a simple regular diet, by self-effacement (dying to live), by light, regular, daily occupation, by the resolution to give a deaf ear to his trying sensations, and by a determined fighting and struggling to lose himself in outward things. . . . To do nothing would be to go backwards and downwards. True, he may suffer if he works ; nevertheless, it is best to work. Hundreds suffer to work. I have always suffered to work, but work keeps me where I am ; I have to wrestle with it, but thus my antagonist becomes my best helper.

Yours sincerely,
ANDREW CLARK.

VACCINATION IN ANCIENT TIMES.

A CORRESPONDENT of the *American Practitioner and News* writes that at a recent meeting of the Epidemiological Society of London Dr. Pringle called attention to the following passage, he had found in an ancient Hindu work, which he thought proved that vaccination was known and practised in India centuries before the birth of Jenner :

"The small-pox produced from the udder of the cow will be of the same mild nature as the original disease, the pock shall be of good color, filled with clear liquid, and surrounded by a circle of red. There will only be a slight fever of one, two, or three days, but no fear need be entertained of small-pox so long as life endures."

A REMINISCENCE OF THE NICARAGUAN FILIBUSTERS.

In a recent number of the *Journal of the American Medical Association* Dr. L. C. Lane describes the condition in which he found the American filibusters who had been taken prisoners by the Costa Ricans in 1858. He was at the time assistant surgeon on the U. S. Sloop *Decatur*, which was moving from port to port for the purpose of aiding or protecting Americans who might be found in distress.

On arriving at Punta Arenas, the Pacific port of Costa Rica, they found a body of American prisoners, most of them under thirty years of age, half-naked, and suffering from starvation. Nearly all were troubled

with ulcers of peculiar type, seated chiefly on the arms and legs and due to wounds received from thorns or insects. These ulcers consisted of half-formed tissue which, in the exuberance of its growth rose two or three lines above the adjacent surface. They were of a pale-yellow color, and so non-vascular that when touched they did not bleed. This pseudo-formation differed widely from any form of granulative tissue, and in appearance it resembled a thick emulsion, rather than an organized animal tissue. In fact, it was a new type of structure, so low in organization that it was the analogue of a fungoid plant, and was no more sentient than the latter. This fungoid neoplasm had arisen in the human body that was saturated with malarial poison, half-starved and living on a non-nitrogenous food. Under the simple treatment of cleanliness and feeding on man-of-war's rations the ulcers rapidly healed.

THE LITHOTRIPTIST.

In a recent address on the progress of surgery during the present century, Professor Clark, of Glasgow, gives the following interesting bit of medical history. Speaking of the great advance in operations on the urinary bladder, he says :

"I have in my possession an old English dictionary, the author of which was James Knowles, the father of Sheridan Knowles, the playwright and poet. In that book, on the usual blank page behind the title, is this note :

"N. B. — Look for a New Word after the last word in P, and a further explanation in an added Page at the end of the Preface."

"The new word thus indicated is *Lithotriptist*, and the meaning is 'A professor and operator in the recently discovered art of lithotripsy ; which consists in breaking, triturating, and pulverizing the stone in the bladder, and removing all the particles of it. The word is here, with thanks to God, a sense of duty to the public, and a deep feeling of gratitude to the Professor Baron Heurteloup, associated with his name ; he having on Saturday the fourth of April, in presence of several surgeons and physicians, in about five minutes operated upon the author, whose age is seventy-three, without giving him much uneasiness ; and by his consummate skill, not only relieved him from a state of suffering, which he had endured for twelve months, but preserved his life, which, in all human probability, he must have lost under the operation of lithotomy.' This book is dated 1838, and we have thus a definite time from which to date the commencement of the operation for crushing stone."

PHARMACY, THERAPEUTICS AND CREDULITY.

PROFESSOR CASH opened the Edinburgh session of the Pharmaceutical Society with an address¹ on some of the present aspects of therapeutics. In tracing the relations that connected the scientific chemist with the therapist, he said it was the part of the chemist to produce a pure substance, so that the pharmacologist might be able to assign to it its definite and proper value. The product once obtained, the question arose, Why do we use this drug ? The answer involved an

¹ British Medical Journal.

answer to the pharmacologist's questions, How is it to be used? which gave scope to the dexterity of the pharmacist to prepare it in many forms for the exigencies of practice; and When should it be used? To this third query the therapist gave the final reply. He it was who, bearing in mind and relying upon the labors of the men who answered the questions, Why? How? applied the accumulated knowledge to the cure of disease. It was not rash to forecast that the advent of new remedies would be through the channels of close research and study, and that the scientific practitioner of the future would refuse to make use of anything which reaches his hands by less certain ways. Pure empiricism was decaying, although its decline was likely to be slow. Credulity was losing its hold on all, and whether the cry was a new cancer cure by green or yellow electricity or a great Chinese cure, the rush of the credulous amongst those who had been educated to know the left hand from the right in medical matters was but a trifling one. Still, it was not likely that this generation nor the next would fail to contribute its numbers to those who chased the will-o'-the-wisp into medical bogs. But credulity might be shaken by firm example, and he hoped much from the confidence that could be justly obtained from what had been weighed in the balance and not found wanting.

THERAPEUTIC NOTES.

LOCAL ANÆSTHESIA.—A mixture of chloroform (ten parts) ether (fifteen parts) and menthol (one part), used as a spray, is recommended as an excellent and prompt means for obtaining local anæsthesia lasting for about five minutes.

CORYZA.—Hayem¹ gives the following prescription for the relief of acute coryza:

R	Acid. carbolic	}			aa	3 iiss
	Aque ammoniac	}				
	Alcohol					3 v
	Aque destil.					3 i M.

Sig. Inhale from several drops upon a piece of bibulous paper.

LOTION FOR PRURITUS VULVÆ.²

R	Hydrargyri perchloride	gr. i
	Alumina	gr. xx
	Pulv. amyli	3 iiss
	Aque menthæ pip. q. s. ad	3 vi

M. et fl. lotio.

Sig. Apply externally to the affected parts.

TO PREVENT COCAINE INTOXICATION.—Professor Parker, in the *British Medical Journal*, states that he has discovered that the unpleasant or even poisonous symptoms which occasionally follow the application of strong solutions of cocaine in the nasal and buccal cavities, may be entirely prevented by combining the drug with resorcin.

AN INHALATION FOR PULMONARY TUBERCULOSIS.—Dr. Carasso Michele, Director of the Military Hospital at Genoa, has used since 1888, in the treatment of pulmonary tuberculosis, constant inhalations of oil of peppermint. He combines the inhalation with the internal administration of an alcoholic solution of creosote, glycerine and chloroform, to which is added oleum menthæ piperitæ, 1:100. His results are reported as remarkable. Not only were incipient cases cured, but advanced cases also, some thirty-nine in all, with cavity-formation and abundant bacilli in the

sputum. All the cases treated were of pulmonary disease only, without tubercular affection elsewhere.

INHALANT FOR ACUTE LARYNGITIS.¹—Casselberry recommends the following combination as a soothing spray in acute inflammation of the larynx and trachea:

R	Ol. pint canadensis	m. v
	Ol. gaultheriæ	m. ii
	Ol. eucalypti	m. ii
	Menthol	gr. i
	"Benzoinol"	3 ii
	"Vaseline oil" q. s. ad.	3 i M.

Sig. To be used with a double-bulb atomizer.

WHOOPING-COUGH.²—Bergeon reports that for six years he has successfully treated his cases of whooping-cough by rectal injection of carbonic acid gas. Immediately after the paroxysm one or two litres of the gas are injected into the rectum provided that three hours have elapsed after the last meal. The injections are repeated every four hours if necessary. They cause no gastric or intestinal disturbance and the child can eat immediately afterwards. Under this treatment his cases usually yield at the end of a week. Unruh³ directs his treatment chiefly to the initial bronchial catarrh, and advises the insufflation of a grain and a half of powdered quinine once a day. In young children where this cannot be accomplished, he uses turpentine inhalations by means of face masks. Internally, he gives every three hours a teaspoonful of a three-per-cent solution of antipyrin, which is the only drug he has found of value. Pizzocaro⁴ calls attention once more to the favorable effect of vaccination upon whooping-cough. In several very severe cases, with twenty or thirty coughing spells a day, which had been unrelieved by the usual remedies, inoculation with animal lymph resulted in a complete cure in from eleven to eighteen days.

Correspondence.

"HIGHER MEDICAL EDUCATION."

CHICAGO, January 10, 1894.

MR. EDITOR:—The following notice will be of interest to many of your readers. Hoping that its publication may induce other colleges to enter upon the same policy,

I am yours truly,

E. FLETCHER INGALS, Registrar.

"In pursuance of the policy recently announced in the resolution to be presented to the American Medical College Association, the Trustees and Faculty of Rush Medical College have decided to require four years' attendance at college from students who begin the study of medicine this year with a view to graduation in 1898; however, those who have already studied medicine one year or more with a preceptor, so that the four years of study, already required, will be completed before July, 1897, may graduate after three courses of lectures, as heretofore. To encourage proper preliminary study, graduates in Arts and Sciences from high-grade colleges, and graduates in Pharmacy and Dentistry from colleges requiring a proper amount of study and two full courses of lectures will, until further notice, be allowed to graduate after an attendance on only three courses of lectures."

[We think announcements of this sort would be more useful if the length of the school year were stated, as well as the facilities for taking a four years' course in three years.—ED.]

Deaths reported 2,446: under five years of age 774; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 306, acute lung diseases 552, consumption 266, diphtheria and croup 131, diarrhoeal diseases 33, typhoid fever 28, scarlet fever 24, whooping-cough 24, measles 22, cerebro-spinal meningitis 6, small-pox and erysipelas 6 each.

From scarlet fever New York 7, Boston 6, Brooklyn and Pittsburg 3 each, Cambridge and Somerville 2 each, Milwaukee 1. From whooping-cough New York 6, Brooklyn 4, Boston, Cincinnati and Pittsburg 3 each, Washington, Charleston, Worcester, Somerville and Taunton 1 each. From measles New York 12, Milwaukee 8, Brooklyn and Cambridge 1 each. From cerebro-spinal meningitis New York and Lowell 2 each, Brooklyn and Washington 1 each. From erysipelas New York, Boston and Washington 1 each. From small-pox New York 2, Boston 1.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 6, 1894.

FRANK C. COOK, Washington, D. C., commissioned an assistant surgeon in the Navy, January 4, 1894.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, January 17th, at 8 o'clock.

Papers: Dr. G. G. Sears: "Pregnancy and Heart Disease." Dr. R. C. Cabot: "Diagnostic and Prognostic Significance of Leucocytosis."

F. C. SHATTUCK, M.D., Chairman.
HENRY JACKSON, M.D., Secretary.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday evening, January 17th, at 8 o'clock, by Assistant Professor Ernst. Subject, "Advances in Bacteriology." Physicians are cordially invited.

RECENT DEATHS.

OLIVER AUGUSTUS WILLARD, M.D., M.M.S.S., died in Lowell, Mass., January 7th, aged thirty-eight years.

FRANCIS MINOT WELD, M.D., died in Jamaica Plain, December 31st, aged forty-three years. He graduated from Harvard College in the class of 1860, and while a student in the Medical School, received an appointment as medical cadet and was soon commissioned as assistant surgeon at the Naval Hospital in Chelsea. During the year 1863 he served on the ironclad monitor *Nantucket* in blockade service at Charleston and Savannah, and later in the year served on the frigate *Wabash*. He was relieved from naval duty in January, 1864, and completed his course at the Harvard Medical School. In April, 1864, he entered the army as a surgeon and was with Grant in the Campaign from the Wilderness to Petersburg, and with the Army of the James before Richmond, and joined Sherman at Raleigh. During his service he was at different times brigade and division surgeon, and in charge of various field and post hospitals. After the war, October 1, 1865, he began the practice of his profession in Jamaica Plain, but moved the next year to New York City, where he practised until 1887. He was medical superintendent of the New York Hospital in 1876-7. He was for twelve years a member of the board of overseers of Harvard University.

HAMPTON E. HILL, M.D., died at Saco, Me., January 9th, aged forty-three years. He was at one time demonstrator of anatomy in the Bowdoin Medical School and a member of the medical staff at the Soldiers' Home at Togus.

LUCIUS FLAGG BILLINGS, M.D., M.M.S.S., died in Barre, Mass., November 26, 1893, aged seventy-one years.

PIERRE J. VAN BENDEN, M.D., D.Sc., LL.D., Professor in the Faculty of Sciences at Louvain, died at Louvain, January 9th, aged eighty-four years. His life was spent in scientific research in many departments of knowledge, anatomy, zoology, physiology and ethnology. He was a member of the Academy of Science of Belgium; a foreign member of the Royal Society of London; a member of the Institute of France.

BOOKS AND PAMPHLETS RECEIVED.

Thirty-eighth Annual Report of the Trustees of the Northampton Lunatic Hospital for the Year ending September 30, 1893.

The Healing of Rodent Cancer by Electricity. By J. Inglis-Parsons, M.D., M.R.C.S., M.R.C.P. (Lond.). London: John Bale & Sons. 1893.

Outline of Physical Diagnosis of the Thorax. By Arthur M. Corwin, A.M., M.D., Demonstrator of Physical Diagnosis in Rush Medical College; Attending Physician to the Central Free and Bethesda Free Dispensaries, Department of Rhinology, Laryngology and Diseases of the Chest. Chicago: The W. T. Keener Co. 1894.

A Text-book of the Physiological Chemistry of the Animal Body, Including an Account of the Chemical Changes Occurring in Disease. By Arthur Gamgee, M.D., F.R.S., Emeritus Professor of Physiology in the Owens College, Victoria University, Manchester; Lately Fullerian Professor of Physiology in the Royal Institution of Great Britain. With two chromolithographic charts by Spillion and Wilkinson. Vol. II. The Physiological Chemistry of Digestion. London and New York: Macmillan & Co. 1893.

Original Articles.

ON THE VALUE OF EXAMINATION OF THE BLOOD OF THE INSANE.¹

BY J. A. HOUSTON, M.D., NORTHAMPTON, MASS.,
Assistant Physician, Northampton Lunatic Hospital.

It is a truism that the mind requires, for the proper maintenance of its operations, a sound body.

You are all cognizant of the influences which mind and body have upon each other. Their interdependence is noted every day by the hospital physician; he sees it in many cases on admission, it having been estimated that in 55 per cent. of admission to hospitals for the insane the bodily health is considerably below normal; he notices it in convalescents by the advancement together of mind and body toward a condition of soundness, the weight-charts of recoveries showing almost universally an upward curve; he realizes it in those cases that retrograde till death seems to result solely from the physical exhaustion induced by the mental state; and finally he admits it by his method of treatment, which is largely directed toward the restoration of the body to its normal tone.

How great a factor impaired vitality is in the etiology of mental troubles is not easy to determine, because in so many of our cases it is a result rather than a cause.

Of 1,678 admissions to the State hospitals of this commonwealth last year, the assigned cause of insanity was ill-health and privation in 74 cases, or 4.5 per cent., while in seven per cent. additional cases the assigned causes were such exhaustive diseases as influenza, phthisis, typhoid fever, pneumonia, rheumatism, neurasthenia, etc.

Inasmuch as numerous agents and conditions which influence the quantity of blood supplied to the higher nervous centres, thus increasing or diminishing the amount of nutriment, do thereby cause disturbances of the normal action of those centres, it has been inferred with reason that marked variation in the quality of the blood-supply may similarly produce impaired action of the nervous centres.

To determine what connection, if any, exists between certain mental states and pathological conditions of the blood, Dr. S. Rutherford Macphail several years ago made an extensive series of examinations of the blood of the insane with special reference to its richness in corpuscular elements and in hæmoglobin.

The results of his investigations, which are published in the *Journal of Mental Sciences* (Vol. XXXII), appear to be quite conclusive that poverty of the blood is in many cases a predisposing cause of insanity. Later observers confirm the results obtained by him.

An account of my experience in the examination of the blood of the insane within a few months past may be of interest to any who have not personally made such examinations. For estimating the number of corpuscles I made use of the Thoma-Zeiss instrument, which is probably the best adapted to the purpose of those made. For estimating the percentage of hæmoglobin several methods are in use. Probably Fleischl's hæmometer is the most accurate instrument for practical use. I made use of Gower's method, which is simple, and which, I am informed by Professor Henry, of Philadelphia, an authority on the subject, is suffi-

ciently accurate for clinical use — probably within two or three per cent.

In my examination of men in sound health, I found that Gower's standard tint for comparison is apparently too high, none of the examinations showing more than 90 per cent. of hæmoglobin. Learning that other observers had the same experience, I made a new standard, as follows: taking blood from 11 men, as many as I could conveniently obtain at the time, whose blood registered 90 per cent. by Gower's standard, I diluted each 100 times with distilled water and mixed the dilutions. Taking the tint thus obtained for normal, I copied it with glycerine jelly tinted with picocarmine, which makes a stable tint. I corresponded with Professor Henry about the matter, who replied: "I have found the standard of Gower's Hæmoglobinometer too high, and am accustomed to regard as normal a blood which contains a normal number of red corpuscles, and of which the color corresponds to 90 or even 85 of Gower's or Fleischl's test. . . . Your method of obtaining a color standard is the only correct one."

Stimulated by the results obtained by others, I had hopes of obtaining satisfactory results in my own observations. But when, after a few trials, some of the enumerations showed an abnormal plethora in apparently anæmic individuals, and other enumerations indicated an immediate need of tonics in those robust to outward appearance and enjoying the blessings of health; and when finally the same individual would be found rich and poor in the formed elements of the blood, all in the same day, I may add that my enthusiasm was somewhat lessened and my faith was tinged with doubt.

My further experience and further knowledge of the experience of others convince me that conclusions based upon single observations are quite unreliable.

There are many opportunities for making an inaccurate estimation of the number of corpuscles. The chief source of error, in my opinion, lies in the qualities of temperament peculiar to the observer — in the method of conducting the observation from the puncturing of the skin for the blood to the final count. As for the errors of manipulation, I will mention those of importance. Pressure on the finger to induce a flow of blood from the puncture is said to disturb the relative proportion of corpuscles and serum. I do not know as to this; it is easily remedied.

Of more importance is the mixing of the blood and diluent. It should be done thoroughly to ensure an equal distribution of blood-corpuscles through the mixture. I believe this can be done with more certainty in the bulb of the pipette than in an open jar with stirring rod, as some observers do. The objection to mixing in the bulb is the difficulty with which the bulb is afterward cleansed and dried. I think accuracy will outweigh inconvenience in the method. I would recommend having the solution for diluting the blood at blood-heat, and would then rotate the pipette from two to three minutes. In my practice I expel nearly or quite half of the mixture, that I may get a drop from as near the middle as possible. I would not recommend the common practice of counting a second drop from the same preparation, because I fear some undue proportion of liquid or of hæmocytes may adhere to the sides of the bulb during the second mixing, which is rendered necessary by the settling of the corpuscles in the bulb while the first count was in progress.

¹ Read before the New England Psychological Society, September, 1893.

The size of the drop placed upon the cell for counting is supposed to influence the result, though, theoretically, from the nature of the cell's construction, the variation should be slight.

And finally, the care with which the corpuscles on the squares are counted has much to do with the result, since each corpuscle counted, in a dilution of 1-200, represents 3,125 corpuscles in the total estimated.

Considering these facts, it is well-nigh impossible for the observers to obtain the same results from the same individual, and even from the same drop of blood.

Dr. Daland, of Philadelphia, has recently sent me a paper embodying the results of examinations of blood by himself. From a study of eight cases counted by himself and Dr. Sadler conjointly, he reaches conclusions which I will briefly notice. First, he states that when the same squares are counted by two competent observers with the minutest care, a difference between the two counts of between 50,000 and 150,000 corpuscles may be expected, 5,000,000 being the normal average. In the case cited by him where he and Dr. Sadler differed by 150,000 in a total of 4,150,000, he must have counted in 64 squares 320 corpuscles, and Dr. Sadler's count must have been 332 corpuscles, a difference of three corpuscles per field of 16 squares, which seems to me to be an error three times too great. I think 50,000 corpuscles should represent the highest limit of difference.

I would state here that I invariably count 256 squares, and feel more confident of results, though it requires more time.

To ascertain the liability of error when two observers count the same squares, my associate, Dr. Holmes, and myself counted eight consecutive cases with care, though not with minutest care. The greatest difference between our counts was 34,000 corpuscles (considerably less than one per cent.), while the average of difference was less than one corpuscle per two fields, as is shown by the accompanying table.

	Dr. Holmes's.	Dr. Houston's.	Difference.
Case No. 1. . . .	5,066,000	5,062,000	5,000
Case No. 2. . . .	5,860,000	5,881,000	21,000
Case No. 3. . . .	5,734,000	5,703,000	31,000
Case No. 4. . . .	5,168,000	5,134,000	34,000
Case No. 5. . . .	4,106,000	4,091,000	15,000
Case No. 6. . . .	4,712,000	4,678,000	34,000
Case No. 7. . . .	4,900,000	4,925,000	25,000
Case No. 8. . . .	5,478,000	5,450,000	28,000

Again, Daland states that when two preparations are made from the same diluted blood, and counted immediately by the same observer, a difference ranging from 187,500 to 525,000 may occur. In my experience I have found liability to error in making the second count from the same mixture, as to the reason for which I have already expressed an opinion. I prefer to verify by counting from a fresh mixture of blood.

Daland further says, "When two observers take blood from the same drop, dilute, and each prepares two slides and counts 128 squares, the results of the two observers may differ as much as 1,881,250."

Dr. Holmes and myself have never been so unfortunate when verifying each other's count by separate preparations of blood. It seems to me that the great differences in results obtained by observers may be due to the small number of squares counted, to differences in the instruments used, and to the personal equation of

the observers. The error from the last cause should be nearly constant.

Dr. Henry has shown that differences in instruments exist; and Dr. Daland shows that his enumerations are almost invariably smaller than Dr. Sadler's.

Dr. Daland considers the hæmatokrit a more accurate instrument. It is designed to exhibit the volume of corpuscles in a given amount of blood by means of centrifugal force.

Referring to the unsatisfactory results obtained by Dr. Daland and Dr. Sadler in blood counting, Professor Wilcox, of New York, in a pamphlet on anæmia, writes that he has abandoned making estimations of the numbers of blood-corpuscles, but continues the use of the hæmoglobinometer.

In spite of the doubts of accuracy thus mentioned, my experience convinces me that much reliability may be placed upon the results. By careful and methodical operation the error should be reduced to three per cent. at the highest. I have numerous cases which I have counted repeatedly, from fresh mixtures each time, and on different days, in which the results agree within a range of one per cent.

When we consider the error peculiar to each observer, the same percentage of variance would seem to attach to each case of a series counted, which series for purposes of comparison would thus not be vitiated; the relative significance of the cases would be just as valuable.

I have dwelt at some length on the question of accuracy in blood counting, because thereon hinges all the value of the operation.

Owing to lack of time the number of cases observed by me has been small, though the number of observations has been several times larger.

In 13 cases, well mentally and physically, whose blood was examined by me I found the average for males to be 5,101,000 per cubic millimetre and for females 4,764,000 per cubic millimetre. Some observers obtain greater, some smaller, numbers than these. The mean of averages by 17 observers, as computed by Dr. Daland, is for males 5,130,000, which is but a fraction of one per cent. larger than the average obtained by me.

Of the insane I examined 25 males and 27 females, as appears in the accompanying table.

These are average cases representing several of the various forms of insanity. The results, which largely confirm the conclusions of other observers, show that in a large proportion of the insane there is marked diminution in the number of red blood-corpuscles and noticeable deficiency of hæmoglobin.

Considerable decrease in the number of corpuscles was found in 60 per cent. of the males (averaging 4,427,000) and in 40 per cent. of the females (averaging 4,196,000). The percentage of hæmoglobin was much below normal in 84 per cent. of the males (averaging 74.3 per cent. of hæmoglobin) and in 77 per cent. of the females (averaging 69 per cent. of hæmoglobin).

Since many of the cases had been under tonic treatment for some time when examined, and since there are in the list but four cases of dementia which of all forms of mental disorder presents the greatest poverty of blood in the elements under consideration, I think an examination of all cases in the hospital would give much lower averages than the above. An analysis of the cases in detail would prove tiresome to listen to. I will give only general results.

I shall make no mention of white corpuscles in the analysis of the cases, because in none did I find any considerable departure from the average number to be found in health.

Reasoning *a priori* would lead to the inference that in those forms of mental disease characterized by quickened mental processes, such as the manias, the blood would be found rich in corpuscles and hæmoglobin — while the converse would be found to exist in psychoses characterized by an abeyance or loss of mental powers as in the melancholias with sluggish circulation and in dementias. Such is in a measure the case, though the relationship between the condition of the blood and the mental state is far from constant.

Macphail says the proportion of corpuscles and of hæmoglobin in mania is equal to or greater than the normal percentages. Dr. W. Bevan Lewis says that in his experience a diminution in the number of red corpuscles is more frequently met with in maniacal conditions.

Of eleven cases of mania (six males and five females) examined by me, there was an excess of corpuscles over the normal average in five males and in three females, a deficiency in one male and in two females. The percentage of hæmoglobin was nearly normal in three males and in one female.

Examination of 22 cases of melancholia shows a marked tendency to deterioration of the blood in this form of disease. In numbers of corpuscles about 50 per cent. of those examined were below normal: 6 of 10 males (averaging 4,272,000) and 6 of 12 females (averaging 4,195,000). All the cases were deficient in hæmoglobin, the males averaging 72.5 per cent. and the females 69.6 per cent. One woman had the large number of 5,260,000 verified by repeated counts on different days. This was a case of melancholia with excitement.

Of four cases of epilepsy, too few to be of much value, two cases were found to be considerably below the normal as to corpuscles: one of these latter cases was counted while the patient was in the status epilepticus. In all the cases the amount of hæmoglobin was subnormal.

As was expected, the percentage of corpuscles and of hæmoglobin was low in the cases of paresis examined, four in number, all males, and still lower in the cases of dementia, three males and one female. The case of paresis which presented the lowest percentage was considerably demented.

The six remaining cases, all females, were cases of primary delusional insanity — paranoia. The results of the examinations in these cases were of much interest. I expected they would register high, probably at the normal average, but was unprepared to find them exceed the normal and by so much. Only one case was below the normal. One case showed more than 6,000,000 corpuscles, verified repeatedly; while five of the cases averaged 700,000 more than the average of females in health, and 860,000 more than the average for males in health. These cases also exhibited a higher percentage of hæmoglobin than did any other class of cases, 86.5 per cent., which is not much below the normal for females.

I have examined several of my cases at intervals to watch the progress of the disease and the effect of remedies with interesting results.

CASE XV. Male. Hypochondriacal melancholia, chronic, no delusions. Patient was pale and weak

at times did not feel able to go out-of-doors. Arsenic had been administered for about a month, with no improvement in mental symptoms or in the number of corpuscles and quantity of hæmoglobin. Iron, quinine and strychnine were then given. In about eight weeks he was discharged much improved. The amount of hæmoglobin had not increased from 76 per cent.; but the number of corpuscles had increased from 4,045,000 to 4,923,000, and he had gained in weight five pounds.

CASE XXVI. Acute mania in a girl fifteen years old. She was much excited and very irrational. The first count, taken during her excitement, showed the number of corpuscles to be 4,820,000 and the percentage of hæmoglobin to be 68. Her weight was 78 pounds. In six weeks from the time of the first count she had become quiet and rational. The second count then showed a loss of corpuscles to 4,360,000, but her weight had increased. Enumeration of corpuscles just prior to her discharge (recovered) showed an increase to the number of 4,775,000. The hæmoglobin had increased (seven per cent.) to 75 per cent. and her weight (20 pounds) to 98 pounds. For a tonic she had taken iron, quinine and strychnine.

CASE XXVII. Female, eighteen years old. Acute mania, with remissions. The first count was taken after she had passed through a period of great excitement lasting about six weeks. She was then quiet and rational, but a little above par mentally. The number of corpuscles was 4,300,000 per cubic millimetre; the hæmoglobin showed a percentage of 50; and her weight was 123 pounds. The second count, taken ten weeks later while she was again excited, showed a loss in number of corpuscles to 4,050,000. The corpuscles were at this time very irregular—in the condition called poikilocytosis. Five weeks later she had become quiet and rational again, when it was found that the number of corpuscles was about the same as at the second count (4,078,000) but the amount of hæmoglobin had increased (17 per cent.) to 67 per cent., and the body weight had increased by four pounds.

CASE XL. Has for a number of years been subject to periods of melancholia attended by delusions and by hallucinations of sight and hearing. Several of these periods have been concurrent with attacks of pelvic peritonitis. In March she was cheerful and as well as she had been for years, weighing about 120 pounds. In April and May she suffered from dysmenorrhœa, followed by peritonitis. She became very melancholy and delusional. In July she was convalescing both mentally and physically. On the first of August she weighed 84 pounds. Examination of blood showed 50 per cent. of hæmoglobin and 4,000,000 corpuscles. The first week in September she was cheerful and rational; her weight had increased 14 pounds; the hæmoglobin had risen (10 per cent.) to 60 per cent., and the number of corpuscles to 4,500,000. The tonic was saccharated oxide of iron.

CASE XXXIII. Female. Acute melancholia, coming on during lactation. At the time of first blood count, July 8th, she was much depressed and very irrational, with some delusions of persecution. Her weight was 130 pounds; percentage of hæmoglobin 74, and number of corpuscles 3,975,000. September 4th, the weight had increased by seven pounds; the hæmoglobin remained at 74 per cent.; but the number of corpuscles had increased to nearly 5,000,000. She is cheerful at present, but mentally rather above par.

Of the cases thus far examined to learn the results

of treatment about 88 per cent. show no mental or physical improvement, and the condition of the blood remains practically unchanged; but these examinations have not extended over a long period, and their number is not large. Macphail says: "The result of investigation, comprising over two hundred observations, would seem to indicate that the four tonics which alone or in combination were most efficacious in improving the quality of the blood may be classed in order thus: (a) iron, quinine and strychnine; (b) iron and quinine; (c) iron alone; (d) malt extract." With him the blood of epileptics was found to improve with use of bromidea, prolonged use having no deteriorating effect.

One of my cases of paresis improved much under a course of iodide of potassium, whether from effects of the remedy or not I am not prepared to say. On admission he was so feeble as to require being kept in bed; and he soon had a syphilitic ulcer appear on his leg. It was thought he would not live long, but he gradually improved. He has gained in weight over twenty pounds; the number of corpuscles has increased by about 400,000, and the hæmoglobin by 10 per cent.; and he is less boisterous and somewhat more rational.

It would be of interest to compare a series of consecutive admissions to a hospital with a similar series of those discharged recovered. Macphail thinks there is impoverishment of blood in more than 50 per cent. of cases admitted; and he says of patients who recover, that the quality of blood improves, and is not much below the normal standard on discharge.

While I am not prepared to endorse the opinion of one enthusiastic observer, that the time is coming when we shall examine the blood of our patients as regularly as we count the pulse and take the temperature, my experience convinces me that such examination will show with approximate accuracy any deterioration of blood in our patients, thus indicating need of, and perhaps line of, treatment, and that it will also aid us greatly in observing the progress of our cases and in studying the effects of remedies administered.

HYPERTROPHY IN THE POST-NASAL SPACE, ESPECIALLY AFTER CHILDHOOD.¹

BY JOHN W. FARLOW, M.D., BOSTON.

THE importance of nasal respiration has been so frequently insisted on in the last few years that there is no need for me to call your attention to it this evening. The post-nasal space, where the horizontal passage through the nose turns to become the vertical passage to the larynx and trachea, should be free from obstructions and encroachments, just as the bent heating and ventilating pipes of our houses should not be choked up or narrowed at the elbows and bends. The fact that air goes through the nose, and the mouth is not habitually open does not, by any means, prove that there is no nasal obstruction. The body can adapt itself to various abnormal conditions and overcome them after a fashion, but the work performed is almost certain to be imperfect in certain particulars. It has seemed to me that a very erroneous idea of the nature of free nasal respiration was prevalent. The post-nasal space may contain a large amount of hypertrophied tissue; the patient may claim that he can

¹ Read before the Boston Society for Medical Observation, November 6, 1893.

breathe well through the nose; he may not be a mouth-breather; he resents the idea that there can be any obstruction to his breathing; he has never had any other nose, and has never breathed better than he does now. But after the removal of the hypertrophy he will confess that he never really breathed well before.

I have seen so many instances of this, and have been told so many times by physicians that such and such a case had no post-nasal hypertrophy because there was no mouth-breathing, cases where I have later removed large, obstructing masses, that I feel the importance of insisting that mouth-breathing is only one of the symptoms of nasal obstruction, and that considerable obstruction can exist without mouth-breathing, especially in adults.

The same holds true of snoring. If the soft palate is pushed forward and kept from applying itself against the posterior pharyngeal wall by large growths behind, it becomes parietic, and easily flaps backward and forward in sleep, giving rise to marked snoring. But the palate may be strong, the obstruction high upon the posterior wall, and snoring entirely absent.

If, then, two of the great cardinal features of post-nasal hypertrophy may be wanting, we should naturally expect that many cases would be overlooked, and such I believe to be the case. The degree of obstruction depends upon the relation of the size of the obstructing mass to the space in which it is contained. In young children the post-nasal space is very small, and a small amount of growth would naturally cause very different symptoms from the same amount in a larger child. If the tonsils are very large, narrowing the throat from side to side and preventing the free play of the palate, a smaller amount of growth behind the palate would suffice to cause more marked symptoms than where the tonsils are small.

If the growth is spread out uniformly on the upper part of the posterior pharyngeal wall, the symptoms will differ from the cases where the growth is massed together near the posterior openings of the nose.

With regard to the frequency of post-nasal hypertrophy after childhood, I should say that such cases are very common. The idea that adenoid disease nearly always atrophies after puberty, leaving no enlarged or diseased structures behind, is entirely erroneous. That many such cases are called nasal or post-nasal catarrh, or are attributed to slight deviations and ridges of the septum, or to large tonsils, prevents them from being properly recognized and placed in the category where they belong. But whoever makes frequent and thorough examinations of the post-nasal space with the rhinoscopic mirror must soon be convinced that a pathological amount of adenoid disease is very common after puberty, even up to thirty-five years of age. At puberty the whole region of the throat enlarges, and more open space for respiration exists in the back of the nose; but the diseased glandular tissue is not so prone to disappear, and continues to secrete, inflame and cause trouble by its presence in a different way, ordinarily, from what it did before.

Let us consider what symptoms we may look for where there is no respiratory obstruction. The post-nasal space is a great centre for reflex action, and naturally resents the presence in it of any growth, just as it would a foreign body. A very common symptom in such cases is a dry, hacking cough, often very per-

sistent and more or less paroxysmal. This is quite apart from the cough due to secretion dropping down into the pharynx. Scraping of the throat and sniffing are also endeavors to get rid of an irritant. I have occasionally seen picking of the nose, and more often an outward forcible expulsion through the nose, an evident desire to get rid of an irritant behind the nose. Particularly in young persons is it important to examine the post-nasal space in cases of obstinate cough. I have seen one case of torticollis apparently caused by the presence of a small, firm adenoid. I have also seen several instances of chorea where the post-nasal congestion and irritation seemed to be a factor in the disease.

The glandular nature of the growth shows itself by profuse secretion, tendency to engorgement and proneness to inflammation. Repeated colds are common, and constant sniffing and a loose cough become a part of the daily life. The secretion dropping in the throat keeps the tonsils and pharynx in a state of congestion and hypertrophy. A gland does not need to be large to secrete a surprising quantity and hence the importance of not overlooking the post-nasal space even when there is good nasal respiration. In acute follicular disease of the tonsils, we should also bear in mind that the follicular tissue of the vault is probably also involved and merits attention. I have seen a number of cases where the faucial tonsils were hardly affected at all, while the pharyngeal tonsil was swollen and covered with a whitish exudation and the constitutional symptoms were very marked. In adults, it is not uncommon to find considerable secretion at the vault, apparently having its origin in old diseased glandular remains. I have seen the same after operation where the follicular tissue had been only partially removed, leaving a certain amount of diseased and secreting gland behind, an argument in favor of thorough removal. I have sometimes thought that the amount of secretion had been increased by the incomplete removal.

I shall say nothing of the bearing that large adenoid masses have on the hearing. Such cases usually have other marked symptoms which attract attention, and hence are not likely to be overlooked. But the smaller growths, less easily recognized, and occurring in adults, have a very great significance as they are apt to be overlooked until the hearing has become quite impaired in one ear, or tinnitus aurium has demanded attention. They act more slowly and accompany or cause the more chronic disease of the hearing. It is the situation and nature of these growths which makes them of such importance to the aurist. Small growths in the fossa of Rosenmüller, which keep the Eustachian tubes closed, swollen and bathed in secretion, require careful removal. I have seen a number of instances where bands, the remains of old adenoid tissue, stretched across from the Eustachian eminence to the vault, interfering with the function of the tube.

While the post-nasal space remains in a state of congestion and hypertrophy, the ear must suffer. I am sorry to say that many of the cases of chronic disease of the middle ear, probably caused by a moderate amount of adenoid disease existing undiscovered for many years, are often not much relieved by the removal of the adenoid growth. I think the attempt should certainly be made to free the tubes and the post-nasal space with the hope of relieving the ears, but the benefit is much less certain to follow than in

the early, acute cases of childhood. This is all the more reason for systematic examination of the post-nasal space at as early an age as possible, even when there are no special symptoms.

The deformed mouth, the high arch and projecting upper teeth, are well recognized results of nasal obstruction. The alienist lays great stress on the high palate as a mark of mental deficiency, but the dentist and the physician who sees much of nasal disease are certainly aware that a high palate often has no connection with mental inferiority. In an article on deformed vaults in the *Dental Cosmos*, for November, 1893, Dr. E. S. Talbot says: "In cases of arrest of development of the bones of the nose, and adenoid growths, when it is impossible for the child to breathe through the nose, and mouth-breathing is a necessity, the jaws are separated, and the teeth not having a resting-place, the alveolar process elongates, and a high vault is almost always noticed; hence the reason why imbeciles, and all degenerates who keep the mouth open, as a rule, have high vaults." There remains much to be learned on this subject. I have seen a number of cases of high palate in children where there had never been nasal obstruction and where the mental faculties were very bright, and also a smaller number of instances of marked adenoid obstructive disease where the palate was not high. Where the palate is very high arched, the post-nasal space is sometimes narrow and very high. In operating in such cases, I have been surprised on removing a large amount of growth to find that I needed to go still higher to a second or even third story of growth before reaching the high vault. Such cases are sometimes deceptive in the rhinoscopic mirror. The post-nasal space being narrow, the growth may look small, and one is surprised on learning the vertical diameter of the growth. When dentists attempt to spread the upper jaw in young persons where the post-nasal space contains a considerable amount of obstructive hypertrophy there is sometimes a degree of nervous irritation caused which renders it impossible for the patient to submit to the spreading-plate. I have seen several such cases with dentists, and not until after the removal of the adenoid growth could the dental work be continued with satisfaction.

The importance of a free post-nasal space can hardly be exaggerated. There may be plenty of room for nasal respiration, there may be little or no secretion, but if the posterior wall and vault are covered to a greater or less extent with a thickened tissue, the voice loses just so much resonance, carrying power, and part of its upper register. Our New England climate is held responsible for many thick, catarrhal voices, but this can be overcome in many cases by attention to the post-nasal space and removal therefrom of secreting and hypertrophic structures. I have seen a gain of several notes in the upper register after the removal of a small, soft mass at the vault. The voice does not tire so soon, and can be used much longer at a time in speaking or singing.

The diagnosis is most surely and accurately made with the mirror. I am not speaking of cases of great mouth-breathing, etc., where the symptoms are very marked, and where the finger readily determines that the post-nasal space is filled, I refer rather to cases where the symptoms have to do with the other functions of the post-nasal space than the respiratory. The upper jaw may be very long, and it may be diffi-

cult to reach the vault with the finger. The patient can tolerate the finger for a short time only, and accuracy in diagnosis is impossible. I once operated, under ether, on a case where I had not made a positive diagnosis. The space between the uvula and the posterior pharyngeal wall was so small, owing to projection of the spine at this spot, that I was unable to see anything with my smallest mirror, and the upper jaw was so long that I was unable to reach the vault, even during anæsthesia.

There is sometimes more hypertrophy at the vault than appears in the mirror, as the growth may be of a fairly uniform thickness, or the vault may be very high and able to contain a great deal more tissue than usual. The probe is an aid in such cases. We often see irregular masses with clefts between, and are surprised to find how far the probe will enter into these clefts, from which there may exude a copious secretion. Such are remains of Luschka's tonsil, which has taken on a diseased action.

The regions near the Eustachian tubes should be carefully examined for bands, or small projections, which interfere with the function of the tubes.

The size of the cavity should be carefully noted, as the smaller the space, the greater the discomfort from a given amount of hypertrophy. I should say that in young persons great enlargement of the tonsils was almost invariably accompanied by a considerable degree of hypertrophy at the vault, especially if there is any mouth-breathing.

Treatment in the mild, soft, secreting cases consists in the use of cleansing sprays and various astringents, such as iodine and glycerine. But most cases will require removal by surgical means. Cocaine serves to diminish the pain, and with the co-operation of the patient, the desired pieces can be removed with great accuracy. If anæsthesia is necessary it should be light, as it is much safer than deeper anæsthesia where considerable quantities of blood may enter the air-passages.

Sometimes caustics or the galvano cautery are of use, especially where the diseased and secreting clefts and sinuses are present. My own preference is for forceps, while others favor curettes and various snares. The important point is to remove all the diseased hypertrophied tissue. The lower pharynx should also be treated whenever there are any large follicles present.

THE EFFECT OF CLIMATE AND ENVIRONMENT ON THE NEW ENGLAND GIRL.

BY J. WARREN ACHORN, M.D., BROOKLINE, MASS.

MAN and the forest, man and the mountains, man and nature grow together. Wherever you find the highest mountains, the mightiest forest, (the forest that knows no ancestry,) the deepest ocean, the most graceful lakes (like those one sees in Switzerland), and hear the roar of the cataract that tells of a mighty river, there the most rugged and characteristic in nature abounds (the climatic conditions being also favorable), there you find the noblest type of man — the finest physically, and if civilization has reached him, and educated minds have helped his own to think, the physically and mentally proportionate man. There you find the most potent man and the most thoughtful; not necessarily the tallest, though the race grows tallest in the tallest country; not necessarily the shortest,

though the shortest usually grow where the hills are stunted; not necessarily the brawniest, though the brawniest grow where the physique is greatest and the heart and the perception and the emotions, as well as the endurance and skill, are all appealed to. When you have that combination of brain and body in keeping with a mighty country and its climate, other things being equal, there man works out the longest life and the greatest measure of happiness and usefulness, for happiness and usefulness depend more upon a well body and a contented mind than upon anything else in the wide world.

Who ever thought of hunting for grizzly bears on the rice islands in the delta of the Altamaha? The fierce Numidian lion is no longer a lion if born in a cage and fed with a fork. The gray wolf of the Michigan forest stands you at bay, and snaps and snarls defiance at your coming. I have seen a whole pack of prairie coyotes disappear at the twirl of a finger. Who ever thought of looking for the white-pine of the Maine forests or the pink-pine of Oregon—the masts for ships that sail the world around—in the coast-plain country about Albemarle and Pamlico Sounds, where only the stunted loblolly grows—rough-barked, all sap, with little heart, standing there with half-starved look among the coarser grasses of the great morass? Who ever thought of looking for the finest type of negro among the sand dunes that rise above the level of the waste places in the Great Dismal Swamp? Why the darkey of the uplands despises the rice-island “nigger”; and the southern planter when he would harvest seeks not the coast-plain idler but the foot-hill dweller. Who ever saw the coast-plain negro seeking a home among the mountains that stretch from Harper’s Ferry to the Mississippi? Never does he do it. The negro of to-day weds the plain. He loves the hummock lands that lie along the Suwanee River far better than the sight of mountain peaks that, rising in succession, overpower his imagination and appear to him but the tents of great giants who are resting for the night but with the morning will go on; and the thought for his life, like the great hills he is gazing upon, makes him superstitious and afraid. Mentally he is not equal to the eternal hills. His cabin home is not found beyond the uplands. His mind is still in the beginning of its thought. Later on he may exchange the plain for the mountains, the muddy lagoon for the crystal lake, the red-running river for the sparkling waterfall, the stunted low-land pine for the mountain valley variety with its longer shatter, whose top sighs an hundred feet in air and the whisper of whose voices make for silence. The Sioux Indian of the northwestern prairies is no match for his neighbor, the Chippewa, whose possessions rise where those of the Sioux leave off. The Sioux knows only his pony and the prairie. His arms are small and his chest narrow; and his strength, aside from his hips, is slight. The Chippewa’s shoulders are broad, his arms powerful and his back strong. His horse is not the prairie pony but the birch canoe. His battle-field has not the sameness of the plain nor has his physique, but the grandeur of the hills and the ever-restless waves of the great inland seas.

I have been trying to show that the country marks the man. The American is recognizable from whatever part of our country he may have come, not only because he is imbued with the American spirit which

crops out and betrays him, but also from his American physique—the elongated head, the fine and transparent skin, the quick-glancing eye, the mobility and flexibility of body, the changing features, the genuine laugh, the nervousness of his movements. But if the four present types of Americans from the north, south, east and west are brought together, their likenesses are not so apparent. There yet remain differences due to climatic influences and the topography of that particular section of country from which he came, environments that declare for him what manner of man he is. Never could I persuade the old darkey woman of the South, the Auntie whom everybody knows, that I was a Southerner. “Ah, boss,” she used to say, “you’s come a long ways north of hyer.”

The Yankee is recognizable everywhere; there’s no mistaking him. The figure of Uncle Sam is the traditional Yankee. Here in New England the people grow tall and lank, and their temperament becomes vital and nervous. I believe the New England people are becoming nervous and dyspeptic, although born in a rugged, picturesque country that is reputed to and should produce a rugged, characteristic race. They eat little and hurriedly; they sleep little; they have a burned-out look that bespeaks nervous strain and malnutrition. They worry and they tremble. The women lose their rotundity and the men strive; and both grow thin.

The Southerner comes among us from the land of flowers and ease, with the grace of one accustomed to repose and leisure; but before the Indian Summer is over and the birds are flown, the feeling that he must hurry begins to possess him, and by the 1st of March he is on the run with the rest.

The foreigner comes to us from the rational-living, slow-going countries of the Old World. At first he is astonished to see us get up from the table and leave him to take his dessert alone. He preaches moderation; but the wild race of the people, and the climate, will not let him have it.

And the German of to-day, whose grandfathers landed here two hundred years ago, is no longer a German in appearance; the country has trade-marked him. In spite of the lymphatic, phlegmatic temperament of his ancestors, who were thick-set, broad-shouldered, beer-loving and sausage-eating, he has the refinement of figure and the vital temperament of the Yankee. “He is the European” as somebody has said, “with a drop of nervous fluid added.”

Gladstone’s longevity may be due in part to this act of his life, that he never cuts a string from a bundle, but takes time to untie the knot. What are we born and living for? Is it to hurry? For money? For dyspepsia? For a pain in the side (the virtues of which we recite every morning at table)? For the bubble of a reputation? Or is it rather for happiness and usefulness, so that some one at least, may say of us when we are gone, that he has been happier and better because we have lived?

At ten, the school-girl is physically the equal of the boy. She can run as fast as he; she can jump as high; she can tussle him down over half the time in a rough and tumble; she can skate; she can slide knee-fashion on a sled. The one thing she cannot do that he can do is, throw a ball; but that is not due to her physical condition but rather to an anatomical difference in the shoulder.

What is it then that between the ages of ten and

twenty kills the girl physically, and establishes upon this continent and particularly in New England, a new disease which the Germans style *Americanitis*—American nervousness? And why, if the boy escapes, in part at least, does not the girl escape also?

And first the boy; the country has marked him for its own. Like the man of whom we spoke at length, he is tall and spare and active. He is a typical child of New England parents. But he escapes; and there are two reasons for his escape. The first is, that he *will* play; that he *will* stay out-doors, *will* indulge in recreation of all sorts; that he *will* not study, that is, will not exert himself to the point of going to bed tired from study, rather than tired from play. That is where he is right. In other words, his physical status keeps abreast of his mental advancement and savors constantly of it, so that at the age of twenty, when his mind is really beginning to get on its legs and think for itself, he has a body back of it that is equal to the demands made upon it. And so he continues to grow. At twenty his physical strength is twice that of the girl with whom, at ten, he used to play as an equal.

Now how is it with the girl? At ten, she is the physical and mental equal of the boy. She is doing the same amount of school-work, brain-work, as the boy, and, if anything, is doing it better. To this is added for each day an hour or two of nerve-work at the piano, or at the easel. By the time she is fifteen her dresses have grown, in length, to the ground, and in weight, beyond what any woman's hips should ever carry. By this she is hampered. In addition to these burdens and drain upon the strength, she is helping her mother in home duties daily. Then because every daughter or young woman at home should know the world and learn to carry herself in it, social exertion and excitement are beginning to crowd upon her and eat up her evenings and prolonged periods of rest. Time for recreation of the physical strengthening sort is denied her. Or, perhaps this is not her case; she may have gone out for work and bread-winning as a stenographer, type-writer and book-keeper combined, to become a sort of an electric machine, an organette that will play three different tunes, with her nerves for wires, and her body for a key-board. This comparison, as you will see, is in favor of the organette as against the girl; for the girl has not only to furnish the music, but she has also to turn the crank.

Our typical girl then, does not only the work of the boy, during the formative years, the growing years, when she is naturally perhaps the weaker vessel, but she is doing also, house-work, needle-work, music-work or painting, or taking care of *possibly* invalids or children. To these must be added social forms of which I spoke, most exhausting demands upon her strength, such as making three-minute calls (which a boy will never do, bless him!) or playing good angel to family hand-downs, stupid people who come and stay and absorb one's time and strength as a sponge absorbs water. Add to this the growing dress and the proprieties that must attend its wearing, its hinderance to free movements, and we have one factor more in the count of the things that go to destroy the health of our school-girls. Woman's dress with her entering the avocations of men is a tremendous negative. Not an element in it belongs to a busy, open, exhaustive life. It was devised under and is a result of conditions wholly at variance with such a life. It is fit only for the retired, protected, domestic living within doors, like

that our grandmothers enjoyed. They dipped candles, made apple-butter by September firesides, pickled meats, and knitted their own stockings. It belongs to the time of homes, and not flats and janitors.

Now, further, add to what I have already summed up the fact that a young woman's work is almost entirely mental, spiritual, or vital, preying upon emotions as well as intellect, all through her school life, and that her physical development is practically cut off at fifteen, when she needs physical training most; that the very best blood in her veins is constantly used to develop her brain at the expense of her body, when it is just as necessary, and more necessary, that the hips and shoulders get their share, since they are the parts physically the most used and needed and abused afterwards, and the first to suffer because they have been robbed. Consider that in whatever capacity she works, the girl of to-day is pitted against men, working under laws set for men, working under negative influences—for in many of the pursuits into which they have entered they are not wanted; and is it any wonder that they grow tall and gaunt and have a burned-out look, and finally break—not mentally, but physically, before they are thirty?

At twenty the boy is just beginning to put on steam. At thirty, if he has not broken himself in some vain effort to get rich in a hurry or wear his father's shoes before he is out of college, he is in a position, both mentally and physically, to do his life-work. But if he has taken the other course, he is on a par with the girl I have been describing to you. At twenty, she has mental development in excess; but at thirty she is only a shell—mentally developed, physically good for nothing. Good for a trip down-town perhaps, or two hours' work in the morning; good for one child, but an invalid after that; good to adorn the end of a sofa for the rest of her life; always a cause of concern and regret for others; never contented; never quite happy; never altogether useful in the best sense. Always, as a bird in a cage, she struggles against the bars that fetter her freedom.

I contend then that whatever we do, it is not so much a question as to whether we have brain enough, but have we body enough? Whatever we do we must keep within the *physical limit*. If one is not held by mental inability, but is held by physical disability, then gracefully accept fate and be guided by that. If, on the other hand, the physique is perfect and never tires, then work as hard as you please and drive the mind of mediocrity to its highest level.

"Going to college, are you?" said an old physician to his son. "Well, if you come out all head and no body, or all body and no head, I wouldn't give a copper for you; but if you come out pretty well mentally and pretty well physically, you'll get along in the race."

"Getting along in the race" is exactly the idea. We cannot all of us be orators or great poets, or great singers. We may have the brain but not the physique, or the physique and not the brain; though on the average I think it is fast becoming, with Americans, not so much a question of brain as physique.

Particularly I think this true here in the East where there is repose of neither body nor mind. This nervous climate is telling upon us, but more upon the physique of our women than upon that of our men. What advantage is it to be first mentally in some accomplishment, as, for instance, first in English literature, if after you get it you spend your life in semi-invalidism.

Of what advantage is it to become an intellectual slab, tattooed with Greek and Latin, if after you are so adorned and honored you can neither work nor walk, but must go to bed with it. If you are acquiring something for the use you intend to make of it — *brod studien* — what does it profit to give all your health and strength to approximating perfection when you never shall be able to use it to any advantage for the purpose for which it was intended?

And now about these women whose occupations are not essentially intellectual. Watch the eight-o'clock girl as she hips it across the Common toward Park-Street Church on the way to some of those great kitchen emporiums down-town, where she stands all day long and sells dippers or diamonds. She is alone. They are birds of solitary passage. She has a business nose and the air of publicity. Shoulders high — she is lugging them. Hips narrow — a fact not infrequently commented upon by the stranger physician in the town. A bunch of clothes hang from her undeveloped hips, practically from the small of her back. She tips forward to offset their weight and settles back to ease the strain. Her life during the formative years fitted her for anything but what she is now doing. She taxes every part of her body every day to its utmost that all through the growing years she unconsciously and unknowingly robbed and starved. From ten to eighteen she was worked and taxed from her waist up, since that time the strain has been from the waist down. Her early attainments, if any, are little called into this daily bread-winning account.

Watch the nine-o'clock girl, as she comes an hour later. She is a little better dressed, a little fresher in look, a little less hurried; but still she has that indefinable something in her general appearance that tells she is working on her nerves, or with them to an extent that is drawing upon her general health and strength. She is the personification of the organette I have already pictured.

And now comes the half-past-ten-o'clock girl. She is well-dressed, with a rounded figure and a lazy air and an expression of intelligence and mental alertness that is both refreshing and pleasing. Perchance she is the rich man's daughter and has lived, a part of her life at least, where the balm and aroma of the orange and magnolia, and the swaying grace of the gray Spanish moss has coaxed her into repose and forgetfulness of ambitions and the cutting north winds of this land of ice and industry. Mere beauty needs no appeal; it makes its own. Physical health with adequate harmony of mind and heart, however, be the woman ever so plain, has its attractiveness and its reward in a long and useful life.

Whenever I hear a young man or woman say, he or she is working on nerves, I know at once that sooner or later, the break will come. And when they do break they break all over. The wreck is often complete. All other parts of the body are servants to the nervous system. The nervous system is the last to be perfected, the last to be matured. It is the last to give way. It is king, but the most unsympathetic of all rulers.

One's head is one's capital city; one's body the outlying country. The city people are consumers; the country people, producers. If the body — the country — is thrifty and prosperous and peopled, in time, and time enough, the brain will be full. But if the city is filled with people in proportion to its capacity, the city is over-peopled in proportion to its capacity.

able to provide for, in time the city, that is, the brain, will starve. In other words, an acute brain by its very activity makes demands upon the body that only a well-conditioned body can supply.

The boys and girls of to-day, born of nervous parents, when they become fathers and mothers cannot but produce children more nervous than they themselves were. The law of hereditary transmission is unerring and never-failing. We are made up of two-thirds of what has been and one-third of what is.

Train the mind, but not at the expense of the body during the formative years. They do better life work hand-in-hand together, since they are mutually dependent and inseparable as links in the golden chain of right life and living. Whatever else we do or don't do, we should keep within the physical limit and be satisfied to stay in that field and upon that plain to which we are fitted, both mentally and physically.

Happiness and usefulness depend more upon a well body than anything else in the wide world. Success in life, as the world sees it, does not necessarily bring happiness. Gratified ambition satisfies only vanity. But vanity satisfied and ambition satisfied — bodily strength *nil*, and the nervous system shattered — what avails it to live?

Clinical Department.

APPENDICITIS, WITH APPARENT RESOLUTION OF ABSCESS; RELAPSE; DEATH; AUTOPSY.¹

BY FRANK E. PECKHAM, M.D., PROVIDENCE, R. I.

THE case which I shall report this evening occurred in the practice of Dr. Coxe, of Riverside, R. I., who has kindly given me the history of the first four days of the disease.

The patient was a young man, twenty years of age. On Friday, November 10, 1893, he went to work as usual; but during the afternoon complained of severe pain over the ileo-caecal valve, and in the evening there were chilly sensations followed by several attacks of vomiting through the night.

On the morning of the 11th the temperature was 101°, pulse 108. Percussion note normal over entire abdomen, but there was considerable tenderness over the region of the appendix. The bowels had not moved in four days. In the evening, the pulse was 120 and temperature 102°. There was a little fullness over the appendix, with slight dulness and tenderness on percussion. During the night there was a severe chill.

On the 12th, the third day of the disease, the condition being unchanged, the bowels were thoroughly evacuated by castor-oil, and in the evening there was some improvement. The temperature had dropped to 100° and pulse to 96. There was less tenderness and tympanites. During the night the bowels moved freely twice.

On the morning of the 13th, the fourth day of the disease, there was a change in the symptoms. There had been no vomiting for eighteen hours. The temperature was 99° and pulse 90. The skin was moist. There was no tenderness, no tympanites. The patient felt better and wanted something to eat. Resolution had apparently taken place. The diet was restricted to milk and lime-water.

On this day, a kind friend brought in some grapes,

¹ Read before the Providence Medical Society, December 4, 1893.

which, of course, were eaten. During the night there was a severe chill, with vomiting, which contained bile for the first time. After the chill there was profuse sweating.

On Tuesday, November 14th, I saw the patient with reference to operation. At this time, while talking, there was another slight chill, lasting perhaps five minutes, followed by profuse sweating. There was no sign of mental disturbance. The tongue was coated, the centre being dark brown. Temperature 102°, and pulse before the chill being about 100 and of fair strength. The abdomen on the left side of median line was soft and easily compressible. No tenderness on pressure. On the right side, there was some resistance to pressure, most marked over McBurney's point, and radiating outward to the median line and upward to the border of the liver. Firm and deep pressure revealed considerable tenderness, but nothing could be felt in the shape of a tumor. There was also slight tenderness near the border of the liver. On percussion there was very slight dullness over the area about McBurney's point, and even with the hand pressed well down during the percussion nothing more definite could be learned. There was some tympanites which was generally distributed over the abdomen.

Here was a case of appendicitis which had reached its maximum on the third day, with apparent resolution on the fourth day.

On the fifth day or during the first twenty-four hours of the relapse, with no palpable tumor, and nothing definite on percussion, the patient being in fair condition, I deemed it best to wait twenty-four hours, and to watch the patient carefully in the meantime. I left about three P. M. on Tuesday; and the patient died in collapse about three A. M. on Wednesday.

AUTOPSY.

The autopsy was performed by Dr. W. W. Hunt, who kindly asked me to assist. Dr. Cox was also present.

The abdomen was opened by a long median incision from the ensiform cartilage to the pubes and also by an incision extending from the lower end of this one diagonally into the area about McBurney's point.

The omentum in the middle and all over the left side and some distance to the right of median line was perfectly healthy. In the right iliac region it was congested and matted together into a bunch. This portion was adherent to the intestines beneath.

On lifting the omentum the intestines were found considerably distended with gas. In the hypogastric, the right inguinal and right lumbar regions, the peritoneal surface of the intestines was congested. In all the other areas they looked perfectly healthy.

Pus was found, to the extent of two or three drachms, free in the abdominal cavity, in the right lumbar region. The intestines were adherent to themselves and to the abdominal wall; everything being bound down to one point, where, when the adhesions were broken up, the appendix was found. It extended outward and upward on the outer surface of the cæcum, being closely adherent. About the appendix was a circular ulceration, nearly as large as a silver dollar. The appendix was easily separated, was congested, but not gangrenous. The ulcer had not extended through the intestinal wall, but the tissue broke down at the slightest touch. This was evidently where the small abscess had existed.

Another small ulcer, about the size of a silver quarter, was found on the anterior surface of the ascending colon near the hepatic flexure. This point was also adherent to the abdominal wall, and the colon was adherent to the liver.

Looking at the case from the post-mortem appearances, it is probable that an operation on Tuesday would have hastened death.

The usual incision would have revealed the appendix and the ulcerated surface to which it was adherent; but whether or not the second ulcer would have been discovered is a question.

The only time that an operation could have resulted favorably was during the first attack; and at this time it was not demanded, as the disease apparently ended in resolution.

It is fair to presume that if the case had been operated as soon as the diagnosis was made, a life would have been saved.

The great question to decide in all cases of appendicitis is, when and when not to operate. There are a few surgeons who have placed themselves on record as being ready to operate as soon as the diagnosis is established, and the tendency of surgical opinion to-day is undoubtedly toward that point.

I offer this case in detail as a plea for immediate operation.

Medical Progress.

REPORT ON DISEASES OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, A.M., M.D.

INFLUENCE OF INFECTION UPON THE NERVOUS SYSTEM.

ROGER,¹ recognizing that all infectious diseases may affect the nervous system to a greater or less degree, admits the following divisions:

(1) Reaction of the nervous system in the course of the most diverse acute affections: fatigue, headache and sometimes delirium and convulsions may occur in the course of all forms of infectious disease. These symptoms may depend upon an accumulation of the noxious substances which are constantly forming in the organism, or upon difficulties of elimination.

(2) By the side of these general phenomena of a toxic order we must place the secondary localizations of the infectious process in the nervous system. We often observe paralysis following acute diseases analogous to the paralysis which follows diphtheria. This paralysis may be transitory and due to no organic alteration, or it may be due to lesions of the peripheral or central nervous system. "We admit for tabes, or rather for all scleroses of the nervous system, what we admit for scleroses of other organs. It is demonstrated by clinical observation and by experiments that visceral scleroses may arise from infection or intoxication. In this way syphilis plays a more important rôle than other infections, and represents a chief cause of the sclerotic process, its localization depending upon the predisposition of the individual affected."

(3) Certain nervous diseases may represent a primary localization of the morbid process, in particular infectious multiple neuritis and acute poliomyelitis;

¹ *Revue générale des sciences.* 15 April, 1893.

others always represent a primary infection of the nervous system, as is the case with hydrophobia.

(4) Infection may be the starting-point of nervous accidents which are sometimes very persistent, but which seem to be due to no material lesion; it may provoke the onset or the reappearance of various neuroses. Hysterical phenomena, epilepsy, paralysis agitans, and especially chorea, frequently present themselves under these conditions. With regard to chorea the author thinks that the influence of rheumatism has been somewhat exaggerated, yet he considers that rheumatism is to chorea what syphilis is to tabes. [Yet the statistics with regard to the two affections show a much more intimate relation between syphilis and tabes than between rheumatism and chorea. REP.]

Many of these facts can be verified by experiments: paraplegia represents in the lower animals an ordinary reaction, observed after the inoculation of all sorts of microbes. The author has even produced experimentally a chronic poliomyelitis of infectious origin, which demonstrates the rôle of infection in the development of certain systemic forms of myelitis; and other observers have obtained analogous results. The microbe acts as poison does, and both may give rise to troubles or lesions which the most elaborate vivisections are incapable of realizing.

DISTURBANCES OF SENSATION IN VISCERAL DISEASE.

Head² has made an extremely valuable and interesting study of the distribution of pain and cutaneous tenderness in visceral disease. He found that the pain was in many cases associated with cutaneous tenderness, and, where tenderness existed, the pain lay in that area. If the tenderness be present at one time and not at another, but if the pain remain, tenderness always makes its appearance in the area said to be painful. The tenderness is not deep-seated, but is purely cutaneous or subcutaneous. One of the best methods of eliciting it is to pick up the skin gently between the finger and thumb, or the pressure of the broad blunt head of a large pin may be used. These areas of tenderness bear a definite relation to the different organs affected, but in many cases they lie at a considerable distance from the organ affected. The pain produced by stimulation is not produced by any action on the organ itself, which may lie at a considerable distance from the tender spot. Again, the tenderness may be on the right side, though the organ affected lies on the left side of the body. The superficial reflexes are usually exaggerated over the tender areas produced by visceral disease. Suspecting that these areas bore some definite relation to nerve distribution, Head undertook the study of the distribution of herpes zoster. The eruption of herpes does not follow the distribution of the peripheral nerves at all, and these areas of the herpes eruption agree with the areas of tenderness in visceral disease; in neither case do they overlap, and they have the same maxima. They are also clearly defined. It is not at all likely that these areas have any relation to the cortical distribution, and, as has been said, they certainly have none to the distribution of the peripheral nerves. The areas of distribution of the posterior roots overlap greatly and the border of anaesthesia is not definite. The areas of herpes and tenderness in visceral disease do correspond most closely to the areas of analgesia in lesions of the spinal segments. (The areas of anaesthesia in lesions

of the segments are less extensive and less definite.) After a careful study of the tenderness in different forms of visceral disease, the author concludes that the pain and tenderness are referred along the distribution of certain somatic nerves corresponding to the different spinal segments, and this sensory supply of the viscera corresponds very closely to Gaskell's³ scheme of their motor and inhibitory supply. The sensory supply is as follows:

HEART.—1st, 2d, 3d dorsal segments.

Cervical plexus [= depressor?]

LUNGS.—1st, 2d, 3d, 4th, 5th dorsal.

Cervical plexus [= vagus?]

STOMACH.—6th, 7th, 8th, 9th dorsal.

Cardiac end from 6th and 7th.

Pyloric end from 9th.

INTESTINES.—[A] Down to upper part of rectum.

9th, 10th, 11th and 12th dorsal.

[B] Rectum.

2d, 3d, 4th sacral.

LIVER AND GALL BLADDER.—7th, 8th, 9th, 10th dorsal. Perhaps

6th dorsal.

Cervical plexus [= vagus?]

KIDNEY AND URETER.—10th, 11th, 12th dorsal. The nearer the lesion lies to the kidney the more is the pain and tenderness associated with the 10th dorsal. The lower the lesion in the ureter the more does the 1st lumbar tend to appear.

BLADDER.—[A] Mucous membrane and neck of bladder.

[1st], 2d, 3d, 4th sacral.

[B] Over-distension and ineffectual contraction.

11th, 12th dorsal, 1st lumbar.

PROSTATE.—10th, 11th, [12th] dorsal.

1st, 2d, 3d sacral, 5th lumbar.

EPIDIDYMIS.—11th, 12th dorsal, 1st lumbar.

TESTIS.—10th dorsal.

OVARY.—10th dorsal.

APPENDAGES, ETC.—11th, 12th dorsal, 1st lumbar.

UTERUS.—[A] In contraction.

10th, 11th, 12th dorsal, 1st lumbar.

[B] Os uteri.

[1st], 2d, 3d, 4th sacral, [and 5th lumbar very rarely].

In unilateral affections the pain and tenderness is very apt to be bilateral, possibly because the organ may receive some fibres from either side of the cord. In most cases if the patient be debilitated, or if the affection persist at all, the pain and tenderness tend to spread to other areas, often very remote from the original area; as is seen by the aching and tenderness in the legs in follicular tonsillitis. Anaemia and fever are very common causes of this generalization of tenderness, which generally occurs in various acute diseases, such as influenza and typhoid fever.

ACROPARÆSTHESIA.

Schultze⁴ describes under the name of acroparæsthesia that form of paræsthesia which is often painful and is localized chiefly at the ends of the extremities. He reports twelve cases, and gives the following account of the symptomatology:

The affection is most common in women (although half his cases were men) who have passed the thirtieth year, and its chief localization is in the hands and fingers. It usually takes the form of formication, but it may increase to actual tenderness and may extend up the arms or legs. The affected parts feel stiff, and fine movements may be slow or limited. The paræsthesia may be worse at night or on waking in the morning ("waking numbness"), and it may be worse in winter. It is usually obstinate and it may last for years. The color of the skin is usually unchanged, but it may be very white and cold during the attacks; it is never red. The sensibility is usually normal, but during the attacks it may be blunted, and hyperæsthesia and hyperalgesia are not uncommon. The nerves are

² Journal of Physiology, vol. vii, 1885.

³ Brain, Spring and Summer Number, 1893.

not tender; there is no atrophy; hysterical symptoms are wanting; the joints are not affected; but the affected limbs may be weak.

Schultze then discusses the various theories which have been advanced to explain the disturbance. He admits that the occasional pallor of the affected parts lends some support to Nothnagel's theory of a vaso-motor disturbance, but this pallor is by no means to be observed in every case, and it is hard to understand why, as sometimes happens, the warmth of the bed should cause arterial contraction. He therefore regards the contraction as merely a co-ordinated symptom. The absence of pain and tenderness, of muscular atrophy and degenerative reactions, and of any progress in the symptoms are all arguments against ascribing the symptoms to neuritis. He recognizes the possibility of pressure on the brachial plexus from connective-tissue changes, and of the influence of cold water or chemicals, but these factors are not of universal application. Central lesions are not to be thought of. It has no relations to any general neurosis, but it has some analogies with neuralgia.

The ætiology is obscure, but in many cases there is exposure to hot and cold, with sudden changes in temperature, and to injurious chemical influences; manual labor has little influence. Many cases occur about the climactic period, but the influence of that change is wholly unknown. In the diagnosis we must distinguish the condition from neuritis, tabes, Raynaud's disease and erythromelalgia. The treatment is not very efficacious. Drugs are of little use, except to relieve pain when present; electricity, warm baths and warm local applications may do some good, but the affection, although never giving rise to more serious consequences, is often very obstinate.

Friedmann⁶ considers the affection to be as independent and individual as neuralgia, yet similar paræsthesia is sometimes seen as a symptom of more serious affections, such as tabes. In itself, however, it is harmless, although annoying and persistent. He divides the affection into temporary and intermittent forms, acute, subacute and chronic, the transitory forms being usually limited to one extremity, possibly extending to other parts, and being often subject to exacerbations. In women the menstrual period often has an influence in increasing the severity of the paræsthesia. The acute form is the commonest, and the prognosis is usually very good. The average case usually lasts either a few days or weeks, or else months or years; intermediate, sub-acute forms seem to be rare. The more persistent forms vary in severity at different times in the day; the paræsthesia is apt to be worse at the beginning of the night, or on waking in the morning. In cases of short duration there may be recurrences, yet they are less common, but there are chronic forms where there are remissions of several months. Friedmann has also seen cases with a different distribution, sometimes involving the region of a single nerve. In cases of simple paræsthesia, without severe symptoms or anæsthesia, Friedmann is disposed to ascribe the trouble to general anæmia, with a weak circulation, and he thinks there is often some cardiac affection, especially a slight amount of fatty degeneration of the heart. General neurasthenia seems of little importance. When cold is an ætiological factor there is often pain, with a burning, swollen feeling, and objective disturbances of sensibility. Friedmann puts

in a third group of cases which begin suddenly, are often unilateral and are associated with vertigo and occasionally are followed by slight paresis, but these cases are probably due to focal lesions in the brain. A fourth class of cases are often accompanied with pain, either in the affected parts or elsewhere, and occur in persons with a strong tendency to rheumatic troubles. These cases are allied to cases of neuralgia and neuritis, where the pain is slight but where there is obstinate and severe paræsthesia and burning. The severe chronic forms are seen usually in women at the period of the menopause. Friedmann is disposed to refer the trouble to two pathological conditions—passive hyperæmia of the extremities, and irritation of the peripheral end branches of the nerves. Acroparæsthesia is a typical mild functional neurosis of the sensory nerves of the extremities. In treatment electricity holds the first place, and tonics and cardiac stimulants are often indicated.

Laquer,⁶ basing his experience of eighteen cases, in women between thirty-five and forty, recognizes the picture described by Schultze, and notes the absence of anæsthesia, nerve-tenderness, motor disturbances, electrical changes, muscular atrophy and cutaneous changes, and he also has not observed the pallor of the hands, nor any angio-spastic conditions. In several of his cases he has noted a previous history of severe labors with profuse hæmorrhages. The distress and burning often became so severe at night as to render sleep difficult. Menstrual disturbances and the menopause were not considered as causal factors. The influence of hard work with the hands seems to Laquer to be of great importance. He is disposed to regard the affection as an exhaustive neurosis.

The subject cannot be abandoned without a brief reference to the paper by Collins⁷ in a recent number of this JOURNAL, in which he holds that the trouble is due to defective innervation in the blood-vessels which causes a low degree of blood-pressure and lack of proper blood-supply to the terminal branches of the peripheral sensorial nerves.

ACROMEGALY.

Claus and Van der Schicht⁸ report an autopsy on a case of acromegaly made two or three hours after death. They were therefore able to obtain the tissues in a fresh state, which enabled them to elicit certain new facts. The lymphatic ganglions of the neck had undergone profound modifications. Their structure had become uniform, and they no longer contained lymphoid follicles. All varieties of white corpuscles were found: those with a single nucleus, with a polymorphous nucleus, and with multiple nuclei, even megacaryocytes and polycaryocytes. The muscular tissue of the neck was sclerosed and atrophied; the nuclei had many budding processes, and the sarcoplasm had undergone a vascular and fatty-granular degeneration. The glandular tubes of the hypophysis of the patient, an old man, were filled with principal and chromophilous cells, both rich in fatty granulations. As intermediate forms existed, it seemed probable that one variety engendered the other. The hypertrophied and acromegalic pituitary gland was necrosed and its constituent parts were liquefied. The parts which had escaped this destruction were formed by a lymphoid

⁶ Neurologisches Centralblatt, 15 March, 1893.

⁸ Annales et Bulletin de la Société de médecine de Gand, Nos. 71 and 72, 1893.

⁶ Deutsche Zeitschrift für Nervenheilkunde, iv, 450, 1893.

tissue analogous to that of the lymphatic ganglions of the neck. Several megacaryocytes and polycaryocytes were also found. There was no trace of the primitive glandular tissue. The organ was poor in blood-vessels, and its degeneration and necrosis was attributed to insufficient nutrition. The thyroid gland showed both atrophy and glandular hypertrophy, and hypertrophy of the connective-tissue structure with lymphoid infiltration. The liver showed fatty degeneration and atrophy of the glandular elements, with a slight lymphoid infiltration in the interlobular connective tissue. There was chronic parenchymatous and interstitial nephritis. There was hyperplasia of the splenic pulp and the follicles of Malpighi. The enlargement of the tongue was due to connective-tissue hyperplasia.

DISEASES OF THE CAUDA EQUINA.

Komayer⁹ has collected twenty-six cases of disease affecting the cauda equina, on which he bases an account of the symptomatology. The affections have the double character of diseases of the peripheral nerves and diseases of the cord. Its resistance and its greater mobility protect the cauda from more frequent lesions, and, furthermore, the lumbar vertebræ are more resistant than the dorsal or cervical. One of the constant symptoms of lesions of the cauda is a disturbance in the functions of the bladder and rectum. There is also more or less paralysis of the lower extremities, the paralyzed muscles rapidly losing their electrical excitability and becoming atrophied. There are very severe pains and paræsthesia. In all cases the sensibility in certain regions is diminished or lost, and the reflexes may disappear. Vaso-motor and trophic disturbances are also noted. The causes of disease of the cauda are traumatism, tumors, and syphilitic, tubercular and inflammatory processes, and the course varies according to the cause. Traumatic lesions are apt to be due to hæmorrhage into the spinal canal. Sometimes there may be hæmorrhage into the canal or the cord and spinal roots, without any lesion of the vertebræ. The symptoms depend upon the seat of the lesion. Ordinarily in traumatic cases, the muscles of the posterior part of the thigh are paralyzed. In meningeal hæmorrhage the course is more benign. Death is often due to purulent infection (bed-sores) or ascending nephritis. Seven out of thirteen cases died within ten weeks, the others made a relative recovery. Paralysis of the bladder, and anæsthesia resist treatment. Lesions of the conus medullaris cannot be distinguished from lesions of the sacral roots. If there has been no injury the disease develops insidiously, and is almost always attended with pain and paræsthesia. The pain is intolerable and is situated in the lumbar and sacral region, extending to the legs. Vesical and rectal symptoms follow, but paralysis of these organs is not so complete as in traumatic cases. In both forms there is impotence. The anæsthesia is also somewhat characteristic. It involves the genitals, the perineum and the posterior parts of the buttocks and thighs. In traumatic cases the conus is more apt to be affected; in idiopathic cases the pain and the greater sensibility of the vertebral column indicate an affection of the nerve roots. The most hope in treatment is from surgical interference.

ACCORDING to a police census, there are nearly four thousand doctors' signs in New York City.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, Monday, November 6, 1893, DR. CHARLES P. PUTNAM in the chair.

DR. J. W. FARLOW read a paper on

HYPERTROPHY IN THE POST-NASAL SPACE, ESPECIALLY AFTER CHILDHOOD.¹

DR. SPRAGUE: I think this is a very important subject. Post-nasal hypertrophies are without doubt the cause of many troubles. As Dr. Farlow has said it is almost a daily occurrence in the clinic to find these cases where the patients have never complained of any nasal obstruction, and in fact almost deny that there is any trouble there. It is surprising how small an amount of hypertrophy will cause a great deal of trouble. I think that the vast majority of cases of deafness, and hypertrophic condition of the middle ear, are due to primary trouble in the naso-pharynx. I remember one case where there were adhesions from the anterior portion of the orifice of the Eustachian tube stretching backward to the posterior pharyngeal wall, so that the tube was almost entirely occluded and thereby backing up the mucous into the middle-ear and causing a great deal of trouble in that direction, finally resulting in mastoid inflammation and requiring operation.

DR. A. COOLIDGE, JR.: Dr. Farlow has covered the ground very thoroughly and very well. I have noticed many of the things of which he has spoken, and agree with him that these hypertrophies are often the unsuspected cause of different symptoms. In addition to the evil results of these hypertrophies, I have noticed in several cases a marked atrophy of the adjacent mucous membrane, and of the mucous membrane lower in the pharynx, apparently as a result, a condition which has been noted by Dr. Delavan in the recent Pan-American Congress. There is no doubt that the adenoid hypertrophies of children sometimes do not atrophy, or only very slowly when persons have attained their full growth; but I think that we can hardly say that this is the rule. The number of children who have more or less of this tissue is very large. In young adults the percentage is not nearly so large. I agree with Dr. Farlow that after the removal of part of these growths, in adults, the remainder often remains apparently the same size for a long time; and I agree with him as to the necessity of thorough removal. Unless the amount of growth is large it may not obstruct nasal respiration; but, as Dr. Farlow has shown, this is only one of the numerous evil results of their presence. In reference to diagnosis, in a full-grown person an unusually long finger is required to reach to the vault, if the person is not etherized. It is very difficult to judge of the amount of hypertrophy with insufficient light. By far the best view of this region I have got by sunlight. In using sunlight it is better to have a flat head mirror, one that does not focus the rays. If such is not at hand an ordinary head mirror may be used, but care must be taken not to focus upon the patient's uvula, which may burn the patient's palate. It is sometimes possible, with cocaine, to thoroughly remove the growths in a few sittings,

¹ See page 56 of the Journal.

without much discomfort, but in many patients the naso-pharynx is too sensitive to make this practicable. A long etherization is often a good deal of an undertaking. I have on many occasions been able to operate very satisfactorily by primary etherization. Everything is ready at hand before beginning the ether; the patient sits in a chair in a position to be operated on; the operator also sits in position. The patient is then told to breathe as rapidly as possible from a sponge well soaked with ether. After breathing in this way for from three-quarters of a minute to a minute, the sponge is removed, a gag immediately put in, and the naso-pharynx cleared with a Gottstein curette and the finger-nail. This gives about from half a minute to a minute of anæsthesia. In two minutes after beginning the ether, the patient has sufficiently recovered to understand directions given him, and in two or three minutes more he is ready to go home. No pain has been felt, and there is never any vomiting. It is not always possible to induce the patient to breathe rapidly enough for this method of etherization, but in many cases of older children or adults, it is very satisfactory, provided that all that is necessary can be done in the short time. In advocating this method of anæsthesia I do not mean to say that I prefer such an operation to the careful removal of all traces of hypertrophy. The latter is the more complete method of treatment and produces better results, but it implies a longer etherization with its attendant discomforts. If after beginning this short operation it is evident that it is impossible to do satisfactory work in the time, it is always possible to prolong the ether.

DR. JACK: The connection between the ear and naso-pharynx is a very important one. Ear diseases are perhaps as largely influenced by the post-nares as by causes operating through the auditory canal. The pharyngeal tonsil probably operates as much if not more than any other one thing in causing middle-ear inflammation. The air is cut off from the air cavity by swelling around the Eustachian tube, or by a piece of growth obstructing the mouth of the tube, producing a collapsed drumhead with possibly fluid accumulations, a condition with which you are familiar.

I am in the habit in my work of paying especial attention to the posterior part of the nose, and try to obtain as free breathing through the nose as possible. Childhood is the time to arrest any tendency to ear trouble. From the attention given to adenoids it seems probable that the number of cases in adults will grow less as time goes on. It has been my custom in removing this growth in young adults to operate under cocaine. The success of this method depends largely upon the patient's self-control. It is better in some cases to do the thing thoroughly in one operation under ether. In children an anæsthetic is absolutely necessary, for the growth should be entirely removed to prevent recurrence. The vegetations may reappear after apparent removal, although it is known to be a rare exception to the rule. The Gottstein curette is useful in removing loose ends left by the forceps, but is not as effective in sinking into the base of the tonsil. Careful attention should be paid to the neighborhood of the Eustachian tubes. The growths are usually soft here, and the finger furnishes a safe and satisfactory substitute for the forceps. Profound anæsthesia is not necessary or safe. Hæmorrhage, as we know, is often copious, and threatens to invade the larynx.

Important as is the position of the head in cleaning the throat of clots, of still greater importance is the action of the larynx in case blood tries to enter it. One early experience with this accident, which fortunately, as I was able to remove the clot, did not result seriously, has made me very careful not to give ether to complete anæsthesia of the throat.

DR. COBB: I have very little to add. I have seen Dr. Coolidge do these operations under primary anæsthesia, and it seems to me a very excellent method. With regard to the forceps in operating without ether, there is a great deal of difficulty on account of the contraction of the soft palate and the danger of wounding it with the post-nasal forceps, even in exercising great care; and I think for that reason in certain cases that the Gottstein curette is preferable. With regard to the diagnosis of these growths simply by the post-nasal mirror, it is not always satisfactory, because the mirror pointing somewhat forwards and upwards instead of backwards, one does not get as satisfactory a knowledge of the posterior wall as he does if he examines with the finger; and often when the naso-pharynx has looked comparatively clean, the finger feels considerable growth on the posterior wall of the vault not shown by the mirror. Therefore, I think both methods practised together are much more satisfactory than reliance on either one of them. The tendency of these adenoids to recur is, I think, interesting in cases where one feels quite sure that one has eliminated them; for even when after examination with the posterior nasal-mirror and with the finger one finds that they are practically gone, one will some years afterwards see signs of them, and I do not believe it is entirely due to lack of radical operation. I think there is certainly a fair chance that adenoids have recurred in these cases. Dr. Jack spoke of a case in which he suspected that he had not operated thoroughly. I think that may have been one of these cases.

DR. H. F. VICKERY: I should like to say that a fatal case of secondary hæmorrhage is reported in the November number of the *American Journal of Medical Sciences*. The operator was called to the little boy just in time to see him die. He makes some valuable remarks on the care which should be exercised.

DR. M. H. RICHARDSON: I have seen this operation performed many times by the specialist in diseases of the throat and nose. Personally I have had no experience whatever with the procedure, this operation being so much out of the field of general surgery. I was glad to hear what Dr. Coolidge said about the dangers of complete anæsthesia; and on this subject I should like to say a word. We are too confident in the use of ether. We feel much safer in giving it than we ought; not as regards its physiological action, but the methods of administration. Whatever dangers there are in the use of ether lie in the latter consideration. It is to the most inexperienced person present that we intrust this most important function. This fault is not peculiar to those presumably the least familiar with the subject; it is the practice of every hospital to have its junior men give the anæsthetic. This practice is open to criticism, it seems to me, not only because it increases unnecessarily the inherent dangers of etherization, but because it may disconcert the operator, and at times embarrass him even more than the operation itself. Whenever possible, therefore, anæsthesia should be at least supervised by an

experienced man. At times, of course, the nurse, or even one of the family, must be intrusted with the ether. I think all operators will agree, however, that the anxieties incident to the operation are much increased at such times.

The first operations I ever saw on adenoids were among the bloodiest in my experience; the hæmorrhage in excisions of the upper jaw does not exceed that occasionally seen in the removal of adenoids. Moreover, in the former operation the head can be put forward and the blood allowed to run out; while in the latter there is nothing to prevent the blood from running directly from the posterior nares into the larynx. It seems to me, therefore, that the only safe plan is either to have the anæsthesia so light that the patient can himself keep his pharynx clear of blood, or to adopt some position, like that of Rose, in which the blood by gravitation leaves the air-passages free.

DR. COOLIDGE: In regard to getting blood into the larynx and trachea, if the patient is profoundly etherized, the danger is great; but I think if lightly etherized, it is not great, provided the person is not cyanotic. If there is anything in the pharynx, cyanosis, with or without ether, is dangerous; for instance, in opening a retro-pharyngeal abscess we sometimes hear that there is danger of drawing the pus into the lungs. I believe that the danger is slight, provided the child is not cyanotic. In operations in the throat it is sometimes tempting to complete a proceeding in spite of the fact that the patient has begun to get blue. Most patients will swallow anything in the pharynx unless they are either profoundly etherized or cyanotic. Occasionally a case is met with, which from the start acts badly. The reflexes do not seem to be quite right. In such cases it is necessary to proceed with extra caution.

DR. DE BLOIS: There is an operation with the head thrown back over a block or pillow, in which case the posterior nares would be filled with blood before any could escape into the larynx. Dr. Major, of Montreal, always operates in this way. In cases of retro-pharyngeal abscess which I have frequently opened, I invariably turned the patient upside down just as soon as I have dropped the knife. In cases where I operate on adults I take them by the hair and push their heads down on the floor, because as soon as you cut into the abscess the rush of pus is more than can ordinarily be cleared even if there is no anæsthesia. There is a great deal of the pus, and it comes with a gush. I never have operated on a retro-pharyngeal abscess under ether. I think they should always be opened without ether, because you should have what assistance the patient can give to keep himself from asphyxia.

DR. SPRAGUE: I was very much interested in the suggestion of primary anæsthesia. About a week ago I had a patient in whom I tried primary anæsthesia. I asked the etherizer to get along with as little ether as possible. As soon as the patient was under primary anæsthesia I had her set up, and operated immediately. I cleared out the vault of the pharynx with the forceps, and the fossa of Rosenmüller with my finger. By the time the patient began to struggle she began to clear the throat, and everything was over. I do not know how long it was. It was not more than three minutes perhaps. I think that ordinarily too much ether is given.

DR. FARLOW: With regard to the use of anæsthetics, ether or cocaine, I spoke of them with reference to adults. Many people, especially young ladies, have a great dread of ether, and prefer to have the growth removed under cocaine, even if there is some pain, unless the amount to be removed is large. I am glad to hear what Dr. Richardson has said about the danger of anæsthesia in these cases. I think the anæsthesia should be very light, and great attention paid to the amount of blood lost. It is important to look after the respiration and the pulse. I have seen patients go into a state of collapse even when the anæsthesia was light and the amount of blood lost inconsiderable. I have seen one case of secondary hæmorrhage. It was in a young man, twenty-five years old, from whom I had removed considerable hypertrophied tissue on several occasions without much bleeding. One afternoon I removed several large pieces with forceps, and thirty-six hours later he had a hæmorrhage which lasted several hours.

I think the mirror by all means the best aid to diagnosis, though the finger often gives valuable information as regards the depth of the growth.

With regard to cases becoming less numerous in the future, this is probably true; but I also think that there will continue to be a great many cases where the hearing is involved, where there is cough and a considerable amount of secretion trickling down from the post-nasal space, keeping the nose and pharynx in an hypertrophied condition—cases which may not have caused any great disturbance in childhood, but which, instead of atrophying at puberty, have persisted and even grown larger, requiring treatment in later life.

SPECIMEN OF GANGRENOUS AND PERFORATED APPENDIX.

DR. M. H. RICHARDSON: This specimen is a very beautiful one. The case is one of extreme interest. It is the third case of appendicitis that I have operated on within the last two weeks where the diagnosis was very difficult indeed—in spite of what has been said as to the ease with which the diagnosis of appendicitis can generally be made.

In the first case Dr. F. C. Shattuck, on the second day after admission, made a correct diagnosis of appendicitis where every one else was wrong. I had made a correct diagnosis of it the first day, and had advised immediate interference, but yielded to the advice of all who saw the case that day—all the more willingly because the type was one almost invariably fatal in my hands; and I was glad to be supported in the plan of waiting, for I wanted to see if any different result would follow the let-alone policy. The next day I changed my mind as to diagnosis, and thought it was not appendicitis. I was influenced partly by the absence of leucocytosis, reported by Dr. Richard Cabot; for this condition had been present in every case of suspected suppuration in which an examination of the blood had been made. Death followed operation in a few hours.

In the next case, seen about two weeks ago, all the symptoms were in the region of the liver, and the appendix was found there. The extravasation had extended up between the liver and the ribs and around the foramen of Winslow. I have no doubt it would have resulted in a large subphrenic abscess.

The third case was exactly like the second. The

patient, a boy of eleven, was taken five or six days ago. The operation was done on the fifth or sixth day — I may say the fatal fifth or sixth. The fourth, fifth, and sixth are the fatal days, and the mortality on these days is frightful. Death results, of course, from the general peritoneal infection. The reason why operations performed on the eighth, ninth, tenth, eleventh days, or later, are more successful lies in the "survival of the fittest" — the general infections have all been fatal, and patients with localized abscesses only survive. This young boy of eleven was taken with vomiting and diarrhoea about a week ago. They sent for Dr. Atwood, of Haverhill, on Saturday, to-day being Monday. I saw the case this morning and found the boy with pain over the liver, and sensitiveness especially marked over the hepatic flexure of the colon. Dulness extended from the crest of the ilium into the lungs. The right lung was flat all over its lower half; respiration 40, temperature 102°, pulse 160. On going through the flank with a long incision I came down on the walled-off ascending colon with the appendix situated externally to it at that point. There was a sero-purulent effusion running up between the liver and the ribs and over the kidney, and as far as I could see to the foramen of Winslow. That the diagnosis of appendicitis is correct, is shown in this specimen by the perforation at the tip, with a small faecal concretion under it. I tied off the appendix, drained and packed with gauze. I have no doubt that there is an infection of the pleural cavity and a pleurisy or some lung trouble dependent on direct contagion. The prognosis is very grave, even from the appendix; and with the trouble in the lungs it seems very severe.²

In appendicitis I do not believe that the peritonitis is often caused by these operations. The infection already exists. Two cases of general infection are apparently precisely alike; the treatment is the same in each; one gets well and the other dies. The reason why one dies and the other gets well must generally be found in the nature of the poison. In one case of general infection we get pure cultures of the bacillus coli communis; in another we do not. In a third we get nothing, or very mild micro-organisms. We are going to find, in the bacteriological elements, the explanation for the prognosis of these cases. Since the first of May I know of at least twenty deaths from appendicitis in this community. You cannot say that they were all due to surgical interference, because many of them were beyond surgical aid, and no operation whatever could be done. From my own experience I can say that the diagnosis in many cases is very difficult indeed; and as to the prognosis, you cannot tell anything about it. Some cases get well where you think there is no chance of recovery, and some you think very favorable, die.

BAPTISM BY BRANDT'S METHOD. — Baptism by immersion was performed in an unusual manner in a Pennsylvania town not long ago. A patient too ill to leave his room was desirous of baptism. A large portable tub was filled with water at the bedside. The man was lowered into it on a sheet quite in the Brandt manner, and the ceremony successfully performed.

² December 14, 1893. These two cases recovered. The last had an empyema on the right side, which Dr. Atwood opened. The abdominal wound closed rapidly. From the appendix Dr. McColton obtained pure cultures of the bacillus coli communis. The infection of the pleural cavity was probably from this microbe, though no cultures were made.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED Meeting, December 18, 1892, the President, Dr. S. B. W. McLEOD, in the chair.

A paper by Dr. T. GAILLARD THOMAS on

THE IMMEDIATE CAUSATION OF THE DISEASES PECULIAR TO WOMEN,

was read by Dr. C. C. Carmalt, Dr. Thomas being unavoidably prevented from being present. There were, he said, four great climacteric periods in the life of the female in connection with which the great bulk of the diseases in question occurred. It could be safely stated that eight-tenths of them took their rise from these climacterics. The first of these was puberty, marked by the development of ovarian activity; the second, marriage; the third, child-bearing; and the fourth, the menopause, marked by retrograde processes in the ovaries.

It was with the ovaries, and not the uterus, that the woman advanced and retrogressed; the activity in the uterus being entirely dependent on the former. The changes in the ovaries constituted the phenomenon, and those in the uterus the epi-phenomenon. During the first two-thirds of the period between birth and the age of puberty the ovaries, uterus and annexa remained almost entirely undeveloped. During the last third, they gradually increased in size, and just before the girl reached puberty developed with amazing rapidity. If, when the time of puberty came the appropriate changes had not taken place, if the uterus had not properly grown or had become misplaced, if the ovaries remained undeveloped, or the Fallopian tubes were impervious, diseased conditions would inevitably arise. If ovarian abnormalities existed, the most serious consequences would result, and the young woman might perhaps become the victim of hystero-epilepsy. If the tubes had become strictured, dysmenorrhoea would be the consequence.

The First Climacteric was a period to be watched with the greatest anxiety. On the first of the month the girl might be blooming and in the full tide of health, on the 15th of the same month she might suffer in a way that would indicate to the experienced physician that she was to be a chronic invalid. A system of appropriate treatment for the existing dysmenorrhoea and other symptoms might be instituted, but if the normal changes had not taken place in the ovaries and tubes, every means would be exhausted in vain, and eventually it would be necessary to perform the humane and entirely justifiable operation of removing the ovaries and tubes.

The Second Climacteric. — After passing the time of puberty in safety the young girl would live in health and happiness up to her second climacteric, marriage, unless she was unfortunate enough to take cold during a menstrual period or suffered from other accidental illness. As a result of marriage she was liable to encounter new ills, the three principal of which were vaginismus, gonorrhoeal infection from specific urethritis in her husband, and abortion. In speaking of the second of these Dr. Thomas quoted from an address of his which he had delivered upon a former occasion. Until twenty years ago, he said, specific urethritis was but lightly thought of. It was to Dr. Emil Neoggerath, formerly of New York, that the profession was indebted for its present knowledge of the enormous importance of this affection as a factor in the etiology

of the diseases of women. He had shown conclusively that behind the strictures in the male urethra produced by gonorrhœa, which were so extremely common, the germs of the disease were liable to linger, and that they were capable, even after a long time, of transmitting gonorrhœal infection to the female, with the most disastrous results. Among the troubles to which it gave rise were oöphoritis, pyo-salpinx, and peritonitis, which were always serious, and might result in death. For a time the assertions of Noeggerath were assailed with bitterness and met with ridicule; but they are now universally recognized as true.

In his (Dr. Thomas's) opinion, specific vaginitis was one of the most frequent and active of all the causes of the diseases of women. Its effects are often simply appalling, and left us nothing as a last resort but the operation of oeliotomy, which might of itself prove fatal to the patient under the circumstances. How common it was for an unsuspecting young man of nineteen to slip from virtue. A few years afterward when he had married, still suffering from a low grade of chronic urethritis, he would give all that he possessed if he could undo the terrible results of that early indiscretion. It was, therefore, highly important that every intended bridegroom should be instructed by his physician as to the necessity of a clean bill of health before entering the marriage state. The existence of the gonococcus should be carefully looked for, and a marital quarantine was as necessary as a quarantine for the ordinary contagious diseases.

The Third Climacteric.—Even in normal labors child-bearing was liable to be followed by serious results. Thus, comparatively slight lacerations of the cervix uteri or of the perineum might give rise to the most untoward consequences. In ordinary conditions of the system such lacerations of the tissues would be but a trivial matter, but in the puerperal state it was to be remembered that there were two circumstances which rendered them of grave significance. In the first place, from the moment of the fixation of the ovum after conception there was a rapid development of all the pelvic organs. Secondly, wounds made in the genital canal was bathed, after the birth of the child, by the lochia, made up of cervical and vaginal epithelium, blood and mucous corpuscles, bits of decidua, and, at times, shreds of membranes and of the placenta. Under favorable circumstances the discharge in contact with the abraded surfaces would set up either a sapræmia or septicæmia, with their attendant evils. When it had become the general practice to carefully examine patients at the time of delivery, and to at once repair any injuries that might have been suffered during labor, the diseases of women would be less numerous than they are at present and gynecologists would have fewer operations to perform.

The Fourth Climacteric.—When we considered the far-reaching nervous influences which attended the process of ovulation, it was not to be wondered at that the cessation of this at the menopause should be accompanied with marked changes. While, however, the importance of the menopause as an etiological factor was admitted, it could not be doubted that too much significance had often been assigned to this. Not infrequently there are other causes of disease, which, occurring at this period, were improperly referred to the menopause. Care should therefore be taken to avoid an over-estimate of its importance and at the same time an under-estimate which might lead us to

postpone necessary operations. Having referred to some of the changes incident to the menopause and its effect upon uterine fibroids and other abnormal conditions, he mentioned vaginitis and especially hæmorrhagic vaginitis and procidentia of the uterus as affections liable to be met with at this period.

DR. GEORGE T. HARRISON dwelt upon the extreme importance of gonorrhœa as a factor in the production of the diseases of women. Perimetritis, endometritis and peritonitis were the common result of latent gonorrhœa in the female, as first pointed out by Dr. Noeggerath, and it was with rare prevision that the latter asserted his conviction that this affection was of microbic origin. It was reserved for Neisser to fully establish the existence of the gonorrhœal germ, and the gonococcus was now as universally recognized as the bacillus of tuberculosis. The diagnosis of acute gonorrhœa was an easy matter. It was in the chronic form of the disease that mistakes were made, and the real cause of many cases of oöphoritis and other serious troubles was thus often overlooked. But, if carefully studied, the clinical features would be found to be characteristic. In speaking of the later infections due to gonorrhœa, he said that salpingitis was rare. Peritonitis due to this cause, was fortunately confined to the pelvic peritoneum, as no ptomaines were generated by the gonococci. From his experience he believed that syphilis was an innocent disease in the female in comparison with gonorrhœa. In this connection he related the case of a young married lady who was attacked with metrorrhagia and violent uterine pain, accompanied with a high temperature; an examination showing the presence of endometritis, salpingitis and peri-oöphoritis. She was placed upon appropriate treatment, and began to improve, when suddenly violent gonorrhœal ophthalmia developed, and, notwithstanding the best efforts of two eminent eye-specialists and the most careful nursing and attention, she lost the sight of one eye entirely, and the other was only saved with difficulty.

We constantly saw young men entering on marriage with bright hopes of offspring, only to see them blasted. Sterility was the almost constant result of this chronic gonorrhœa, and women affected with it were liable to protracted ill health. Hysteria was frequently associated with their sterility.

DR. H. J. BOLDT said that while the principal causes of the diseases of women were given in the paper, there were a few points which had not been touched upon. Among the etiological factors were dress and the neglect of hygiene. High-heeled shoes had long been a potent cause of trouble by placing the pelvis in a bad position. Personally he believed that the agency of gonorrhœal infection had been exaggerated, and that the puerperal state (including abortions) was responsible for more ailments than this. Still, we should not underestimate this factor. It was not the acute form, but the chronic which gave so much trouble. In the acute stages of the disease we could, as a rule, cure the patient completely. In the chronic there was apt to be an atrophic form of parametritis, with only slight thickening of the broad ligaments.

Another point to be considered was, what amount of trouble is produced by uncalled-for gynecological interference. He had known pessaries, unadvisedly employed, to produce intense pelvic irritation, and related a case in point. A patient took cold and suffered from pelvic pain. Her physician diagnosed malposi-

tion of the uterus and introduced a pessary, and this had the effect of setting up metritis and double salpingitis. Yet when he (Dr. Boldt) made an examination he found that the uterus was not out of place at all. In other cases he had known the treatment for dysmenorrhœa by dilatation, divulsion, etc., to result in metritis, salpingitis and ovaritis. In all such procedures it was necessary that the patient should be fully prepared beforehand, and he looked upon the simple introduction of the uterine sound as as much of an operation as larger operations. In any case presenting itself it was important to decide whether the patient should be treated at all, and it was without doubt a fact that hundreds of women suffer from unjustifiable interference.

The suppurative diseases of the generative organs were more frequent causes of trouble than gonorrhœal infection. It was, however, impossible to make a differential diagnosis between gonorrhœal and non-gonorrhœal conditions, and we could only surmise that women were suffering from specific trouble who remained sterile for a number of years, (without any other assignable reason,) and had constant pelvic disorder. In all cases where there was sterility without an evident physiological cause he claimed that no treatment should be undertaken for this condition until a microscopical examination of the semen of the husband had been made for the presence of spermatozoa. Exposure to cold during menstruation was, of course, a generally recognized cause of disease in women.

DR. A. H. GORLET said that one common cause of trouble was neglected dysmenorrhœa previous to married life, and it was one that was very apt to be overlooked. He related an illustrative case and then called attention to an association which he had noticed between fibroids of the uterus in married women with dysmenorrhœa during maidenhood. Having referred to neglect of proper care of the bowels as a potent cause of pelvic disease, he spoke of abnormal obliquities of the pelvis produced by faulty positions, in assumed attitudes, certain occupations, etc., as another common cause. He also mentioned tight-lacing and improper suspension of the clothing, and to improper interference of the physician, said he would add improperly executed uterine operations. In all such procedures we should use as much care to secure perfect cleanliness as in operations in the peritoneal cavity, and that we should have as much respect for the uterine cavity as for the peritoneal.

DR. E. E. TULL said that deformities of the pelvic organs were found in a considerable proportion of cases where the individual had received all proper care during early life and was in all other respects perfectly healthy. This was usually, though not always, to be explained as the result of scarlet fever or some other exanthematous disease occurring at the age of 12 or 13. In some cases pelvic disease was due to syphilis, and in one case of oöphoritis where he had removed one of the ovaries, he found gummata in the organ. The patient was at once placed upon anti-syphilitic treatment, and was thus saved from another operation, for the removal of the second ovary. Gonorrhœa he believed to be the most potent cause of pelvic inflammations, although it was very difficult to make a positive diagnosis from the fact that it was rare to find a man who had never suffered from gonorrhœa. Another frequent cause of trouble was neglect of proper cleanliness of the genital organs, and the accu-

mulation of foreign matters in these parts, he believed, often resulted in a mild septicæmia. To this should be added lack of proper cleanliness after childbirth. As to displacements of the unimpregnated uterus, he believed that they were of no importance whatever from an etiological point of view, and that it was a mistake to suppose that they gave rise to any trouble.

DR. BOLDT having asked whether Dr. Tull meant to say that he favored the use of the douche after childbirth, the latter replied that he would not recommend the douche as a uterine treatment. After the third or fourth day he believed it to be of value, but he would not employ it immediately after delivery on account of the danger of introducing infectious material into the uterus.

DR. HARRISON said that he wished to go on record as protesting most earnestly against the practice of vaginal irrigation after childbirth. After normal parturition the vaginal canal and uterus were entirely free from septic material, and said he had the authority of the greatest of all obstetricians, Credé, for this statement. Personally he had performed all manner of obstetrical operations, and neither before or after them did he employ the douche. All that he required was that the operator and everything that came in contact with the woman's parts should be aseptic. Septic hands and instruments were a common cause of puerperal infection. Dr. Harrison said he also differed with Dr. Tull in regard to the importance of uterine displacements. He believed that retroversion was always pathological and a cause of trouble, and that it should be rectified.

DR. ROBERT MURRAY spoke of the practice that had prevailed of late years at the Maternity on Blackwell's Island, where he is one of the attending accoucheurs. The same care as regards cleanliness was used in all cases of labor there, as surgeons were in the habit of employing in laparotomy. At the beginning of labor and just after the birth of the child a creoline douche was employed, and at all other times an antiseptic occlusion-pad (in which a bichloride of mercury solution, 1 to 4,000, was employed), was kept closely applied to the vulva. The results were equal to those of any other maternity hospital in the world. From October, 1890, to October, 1893, there were 957 cases of labor, with not a single death. In 110 of these the forceps were applied at the middle strait or the outlet, in 12 at the superior strait, before the head had engaged at all, in 28, version was performed, in 8, craniotomy, in 1, Cæsarian section, and in 2, symphysectomy. Dr. Murray believed that the great cause of disease in married women, was the bad treatment of childbirth and miscarriage. After the latter they were especially apt to act imprudently. In unmarried women (setting aside the effect of tumors), he thought the great cause of trouble was the lack of knowledge as to how to take care of themselves during the menstrual period.

DOCTORS' BILLS AS DEBTS OF HONOR. — Doctors' bills are said to be classed as debts of honor in Austria, China and Sweden. They are left, as gambling debts are here, so far as the law is concerned, to be paid or not, according to the inclination of those incurring them. This way may not, however, be entirely a disadvantage, because it is well known that such obligations are frequently paid where legal debts could not be collected.

Recent Literature.

The Physician's Visiting List for 1894. (Lindsay and Blakiston's). Philadelphia: P. Blakiston, Son & Co. 1898.

This conveniently arranged visiting-list is now in the forty-third year of its publication, and deserves the continued success which it has met. The various tables upon doses, poisons and antidotes, disinfectants, diseases of the eye, asphyxia, examination of the urine and utero-gestation are well arranged for reference.

A Syllabus of Lectures on the Practice of Surgery. By N. SENN, M.D., Ph.D., LL.D., Professor of Surgery, Rush Medical College, etc. Philadelphia: W. B. Saunders. 1894.

The title describes accurately this volume, which is compact, of convenient size, and contains 211 pages. It is clearly and concisely written. Its contents are arranged in tabular form, with broken lines and separated headings, so that a particular affection is readily found. It is a syllabus in the true sense of the word. The work is arranged in conformity with "The American Text-Book of Surgery," and whenever the text was deficient, the writer has added facts and names of authors and operation. It is practically an index, and a very good one.

Descriptive Catalogue of the Anatomical and Pathological Specimens in the Museum of the Royal College of Surgeons of Edinburgh. By CHARLES W. CATHCART, Conservator, Fellow of the College. Vol. I. The Skeleton and Organs of Motion. Edinburgh: James Thin. 1893.

The Museum of the Royal College of Surgeons of Edinburgh dates from the end of the last century. The former printed catalogue was published in 1836; but as it contained only the specimens illustrating pathology, the present catalogue is in no way a continuation of the old, but rather a new and more systematic arrangement of the collection. The labor involved in new classification must have been great; but Mr. Cathcart has given the college a catalogue which is far more than a list of specimens. It is a book which has a value in itself, and which is made readable, even to the stranger, by the short clinical notes added to the cases.

Clinical Gynecology. Being a Hand-Book of Diseases peculiar to Women. By THOMAS MORE MADDEN, M.D., F.R.C.S., Ed., etc. With 259 illustrations. Philadelphia: J. B. Lippincott Co.

This work embodies forty-seven lectures, which contain the results of the author's teaching, extending over a quarter of a century. They have been thoroughly revised and put into form for publication, and the result is on the whole very satisfactory.

It covers the whole range of gynecological subjects, and even includes the diseases and abnormalities of pregnancy, which, with the exception of ectopic gestation, are not usually treated in a work of this kind.

The general tone of the work is conservative and safe, perhaps too much so for our American ideas, inasmuch as he rejects entirely various operative procedures which have proved their usefulness and their right to be employed in suitable cases. For instance, he does not recommend the employment of the Alexander operation, and utterly rejects ventro-fixation

as a cure for obstinate and adherent retro-displacements.

The book, taken as a whole, is interesting and instructive reading. The illustrations are not quite up to the standard of the latest works on gynecology, and some of them have outlived their usefulness.

A Dictionary of Medical Science. Containing a Full Explanation of the Various Subjects and Terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, Pharmacology, Therapeutics, Medicine, Hygiene, Dietetics, Pathology, Bacteriology, Surgery, Ophthalmology, Otology, Laryngology, Dermatology, Gynecology, Obstetrics, Pediatrics, Medical Jurisprudence, Dentistry, etc. By ROBLEY DUNGLISON, M.D., LL.D. Twenty-first Edition, thoroughly revised and greatly enlarged, with the Pronunciation, Accentuation, and Derivation of the Terms, by RICHARD J. DUNGLISON, A.M., M.D. Philadelphia: Lea Brothers & Co. 1893.

This Dictionary needs no introduction to the medical public. The former editions were the standard medical dictionary for many years. The last was issued in 1874. Since that time, and especially within the last ten years, a number of rivals of greater or less pretension have laid claim to public favor.

With the great progress and many changes in medicine and the allied sciences during that time, a new edition was much needed, and we are glad it has been supplied. Forty-four thousand new subjects and terms are contained in this edition. The volume is enlarged; but by rigid condensation and the omission of obsolete matter the dictionary is still kept within the limits of one volume—a large volume it is true, but not unwieldy or inconvenient for consultation.

The title-page gives the scope of the work and the aim of the editor, which have been faithfully and judiciously executed. Without entering into detailed criticism, and admitting frankly at once that any such work must necessarily exhibit some errors and some omissions, we do not hesitate to recommend this old friend in a new form as once again admirably adapted for every working medical library.

Sciatica: A Record of Clinical Observations on the Causes, Nature, and Treatment of Sixty-eight Cases. By A. SYMONS ECCLES, M.B., Aberd. Small 8vo; pp. viii, 88. London: Macmillan & Co. 1893.

This little monograph, which was originally published in the *Practitioner*, states nothing that is new with reference to the cause or the nature of sciatica. Based on a limited number of cases, the author states a few well-known facts, but he has omitted to give the results of more thorough recent observations,—much of the work is devoted to the treatment. He commends rest, warmth, massage and electricity, swinging the leg in a Salter's swing, and swathing it in flannel. He commends ironing the leg with a hot flat-iron electrode. The book is clearly and pleasantly written.

DR. KENT, in the *Glasgow Medical Journal*, says: "I would make the degree in Arts compulsory upon all candidates for the degree of Medicine and Surgery, and I undertake to say that not one medical graduate of five years' standing out of a hundred would, upon looking back, consider the time spent over his Arts course had been wasted."

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JANUARY 18, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 268 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
268 WASHINGTON STREET, BOSTON, MASS.

REPORT OF THE MASSACHUSETTS STATE
BOARD OF LUNACY AND CHARITY.

THE State Board of Lunacy and Charity, in its Report for the year 1893, makes five recommendations for legislation:

- (1) A separate hospital for epileptics.
- (2) The appointment of medical examiners in lunacy by local judges, as in New York.
- (3) Six months' residence in the State as a prerequisite to a commitment to a State hospital for the insane, in order to avoid having insane persons brought here from other States for the sake of being committed to our hospitals.
- (4) Authority to transfer insane patients from the hospital for dipsomaniacs and inebriates to one of the hospitals for the insane without new commitment papers.
- (5) A medical registrar for each of the hospitals for the insane, whose duty it shall be to keep the hospital records, which are now quite imperfect.

The Massachusetts law provides for the ordinary commitment of an insane person to a hospital for the insane by the judge upon the sworn certificates of two physicians, each of whom is a graduate of some legally organized medical school, and has practised three years in the State, and neither of whom is connected with any hospital or other establishment for treatment of the insane, emergency cases being committed by the judge within five days after the patient is placed in the hospital, with the least possible delay, and under proper restrictions to prevent abuse. There is no penalty if unqualified physicians sign certificates, or if judges accept their certificates without sufficient scrutiny of their qualifications. On the whole, our law has worked reasonably well in all respects and remarkably well in most respects, although certificates of insanity are sometimes valueless by reason of their meagreness and incompleteness, as happens under all laws and in all countries, England and Scotland even included. In November last, a patient was received at one of the State hospitals, committed in due form

by the judge, but upon the certificates of two "doctors" possessing diplomas of a bogus medical college, in violation of the statutes. The patient was discharged as not insane two days later, after a brief examination of the evidence as to his insanity, although it is only fair to say that in court his insanity was testified to by one of the leading experts on insanity in the State. In commenting on this case, the Board says:

"In New York, any judge of a Court of Record may qualify a physician properly recommended as an examiner in lunacy, and give him a certificate to that effect, and no mittimus can be signed by a physician not a qualified examiner in lunacy. This would seem to be an excellent provision in lunacy laws, and the Board recommends its adoption in this State."

It is not difficult for a respectable general practitioner in New York to get his certificate, which is simply an official declaration of the qualifications required by the Massachusetts law, except in its limitation as to being connected with any institution for treating the insane; and the question of the insanity of the patients committed, there as here, "must of necessity fall to the superintendent of the hospital to which they are committed," especially in some doubtful or difficult cases, where "judges of courts of record appear to be going farther than the actual requirements would seem to justify. If this tendency continues in any marked degree, it will be necessary to have such cases determined by the courts."¹

The New York law also has its difficulties, and experts are by no means agreed that it is in any way better than ours, except that it would be a great gain if our Central Board should provide uniform and complete blank certificates for commitment, and if their use should be required in all cases, as is the law in New York. Our law is so liberal and flexible that many fear that the effect of calling the attention of the legislature to it would be to make it worse than it now is, as has been twice unanimously voted by the councillors of the Massachusetts Medical Society.

The Board urges the necessity of frequent inspection—in fact, of a supervision at night as constant as that by day—and of some appropriate way by which patients can be inspected in their rooms at night without being disturbed. Certain established rules of precaution are seemingly more uniformly followed in other States than they are in Massachusetts, where the institutions for the insane show a wide difference in the manner in which night-supervision is conducted.

The law concerning commitments to the Westborough Insane Hospital permits those desiring homœopathic treatment to be sent there at their own or their friends' request. When patients are sent from Suffolk County to Westborough, those desiring other treatment than homœopathic have no option in this matter. There are disadvantages connected with this liberality of method.

The Board recommends laboratories for scientific

¹ Fourth Annual Report of the New York State Commission in Lunacy, Albany, 1893, pp. 246 and 247.

research, medical-improvement clubs and training-schools for nurses in all hospitals for the insane, and suggests that all patients be photographed upon admission, as is done at the Westborough Hospital, by which means escaping dangerous patients might be identified. Occupation is advised so far as it is practicable to employ the patients, and "something more than a long-existing routine treatment, into which it is easy to lapse, may properly be looked for in Massachusetts hospitals."

Of the hospital for dipsomaniacs and inebriates, the Board disapproves of too much lenity and consideration, and an indulgent parole system for drunkards, suggests enforced labor and discipline, and condemns the looseness of many of the commitments, by which "an accumulation of inmates of disorderly and criminal habits and tendencies imperil the success of the humane venture of the State in its effort to treat habitual inebriety of itself by just and rational methods."

A striking case is cited by the Board, which illustrates the possibility of gross abuse in the face of laws prepared with the greatest care for the protection of the insane and hospital management second to none in the world in its solicitude for the welfare of its patients.

A private patient who had been in the McLean Asylum twenty-seven years, legally committed and detained, with the late Dr. Isaac Ray as one of his certifying physicians, seventy-five years old, demented and subject to convulsions which were increasing in frequency, was summarily removed by a deputy sheriff with a writ of *habeas corpus* and placed in the hands of strangers in one of our large hotels, his old attendant and his guardian being denied access to him. On the fourth day he was returned to the asylum, the judge deciding that his commitment was legal. On the following day the judge passed a further order, setting out that it was conceded that — was not of sound mind, and that he was properly in the custody of the asylum; and after reciting that it now only "remained for the court to inquire whether it is best for said — to be further kept and cared for at said hospital, or in some other manner," appointing a guardian *ad litem*, "charged to care for his interest in this investigation, and particularly to inquire in such manner as to him shall seem best, and to report to the court at such time as he may find it convenient, whether it is best for said — to be cared for in the said hospital, or in some other manner, and if in some other manner to report to the court some scheme for his care." The guardian *ad litem*, after a careful investigation, lasting more than two months, reported to the court that Mr. — had better remain in the hospital; and a final decree was entered, dismissing the original petition, and remanding Mr. — to the custody of the hospital. In the ultimate result, therefore, it may be said that no wrong has been done, either to the hospital or to the patient confined there; but the whole proceedings have been so extraordinary, and so inconsistent with the carefully-guarded provi-

sions of our statutes relating to the insane, and to the powers and duties of the judicial and other officers of the Commonwealth as to such persons, that the case should receive a more extended consideration.

With the evidence which we have given in the two cases mentioned and in the quotation from the report of the New York Commissioners, it may be doubted whether the medical profession would be ready to give to all judges the discretionary power of appointing permanently such examiners in insanity as they might see fit to appoint.

THE MICROBE OF SCARLATINA.

DESPITE the progress of bacteriology, the pathogenic microbe of scarlet fever still remains undetermined, unless, in fact, the views enunciated by Bergé at a late meeting of the Société de Biologie (December 10, 1893) should find acceptance. He states that it is useless any longer to search for a new microbe as the cause of this disease, and that scarlatina is primarily a local disease, with secondary infections (the eruption, etc.) due to the formation and absorption of toxins; the pathogenic agent is the streptococcus pyogenes, the microbe of erysipelas, of puerperal septicæmia, etc. In common or tonsillar scarlatina, the streptococcus finds a rich culture field in the crypts of the tonsil and there secretes (in all probability) "an erythematogenous toxin," whose diffusion throughout the organism produces the cutaneous or mucous eruption.

Bergé remarks that the tonsillar affection takes precedence in order of time, and that while the microscope invariably reveals the presence of the streptococcus in the tonsillar crypts, bacteriologists have never found microbes in the cutaneous exanthem, even by the recent methods of research formulated by Nicole.

Puerperal and traumatic scarlatina results from the local streptococcus-infection of the uterine (or other) wound, exception being made of morbid coincidences and of cases of tonsillar scarlatina which may be met with in the course of certain epidemics of puerperal fever, and are sufficiently explained by the existence of the common infectious agent, the streptococcus. It is admitted, moreover, that there may be scarlatina without eruption, characterized exclusively by the angina.

The principal arguments on which this writer bases his conclusions may be summed up as follows: (1) the succession of the eruption to the tonsillitis in common scarlatina; (2) the fact that careful observers have never found the tonsillar affection absent, even in certain rare cases where its presence was overlooked and denied (the so-called *scarlatina sine angina*); (3) the existence of a scarlet fever, really without amygdalitis, of uterine or traumatic origin; (4) the existence of a scarlatina without eruption in which the streptococcus-tonsillitis and its complications constituted alone the disease; (5) the constancy of the streptococcus in the tonsils of scarlatinous patients; (6) the streptococcic nature of the complications of scarla-

tina; (7) the relations of scarlet fever to the puerperal infection; and, lastly, the ready demonstration of the "erythematogenous" property of the streptococcus (pyæmic eruptions, infectious erythema of bucco-pharyngeal origin, etc.).

These conclusions are also corroborated by the study of the clinical comparison between the acute amygdalitis (generally due to the streptococcus) and scarlatina (contagiousness, the same duration of the incubation, the same possible complications, similarity of the febrile cycle, the same symptomatology, save the eruptions, etc.).

The diffusion of the infectious agent is no argument against the view advanced; we know only in part its modalities and its divers pathogenic actions. The non-recurrence of the disease can be affirmed only in respect to the eruption; the tonsillar affection may return again and again with the same violence.

It can hardly be said that M. Bergé's theory, which we have endeavored to state above, explains anything more than the complications and sequelæ of scarlet fever in connection with which a variety of common microbes, and in particular the streptococcus, have been found; it does not sufficiently explain the specific eruption, nor can it be said that this is identical with the erythema of puerperal infection. It will now be in order for M. Bergé to isolate the specific "erythematogenous" toxine, and show that it is produced by some "modality" of the streptococcus; then his chain of evidence will be complete.

MEDICAL NOTES.

PROFESSOR SENN'S GIFT TO CHICAGO.—Prof. Nicholas Senn has given his entire collection of medical books to the Newberry Library of Chicago. A large part of this collection was once the library of Prof. William Baum, of Göttingen. Dr. Senn retains only his working library; all the others are now at the use of the medical profession of Chicago. The money value of the collection is estimated at fifty thousand dollars.

A FOUR-YEARS' COURSE AT JEFFERSON MEDICAL COLLEGE.—At a meeting of the Faculty of Jefferson Medical College held on January 8, 1894, it was unanimously resolved to institute a compulsory four-year course with the session 1895-96. This step was taken in order that the large clinical service of the Jefferson College Hospital (350 cases a day) might be utilized to the fullest extent in carrying out the desire of the Faculty to provide advanced medical education of a practical character.

THE CAMERON PRIZE.—Mr. Victor Horsley has been given the Cameron Prize of the University of Edinburgh for the last year. The prize consists of the income from a sum of £2,000, and is given annually "to the practitioner or member of the medical profession who shall be adjudged to have made the most valuable addition to practical therapeutics during

the year preceding; and in determining the word 'therapeutics' shall be taken in its widest sense as including every agent or agency capable of influencing the human body in the maintenance or improvement of health, avoidance or cure of disease, or the alleviation of suffering."

THE ROME MEDICAL CONGRESS.—The International Medical Congress at Rome will have no lack of papers. Already a thousand articles have been given a place upon the programme. Up to the middle of December there were nearly four thousand names registered of persons intending to be present to listen to the one thousand papers.

AN INTERESTING JENNER RELIC.—The prevalence of small-pox in England, and the insufficient protection of the people by vaccination was a fitting time for the discovery of an interesting relic of Edward Jenner not long ago. At a sale of unredeemed pledges at a London pawnbroker's, there was purchased the casket in which the freedom of the city of London was presented to Jenner on the 11th of August, 1803, for "his skill and perseverance in the discovery of, and bringing into general use, the vaccine inoculation."

BOSTON AND NEW ENGLAND.

SMALL-POX IN BOSTON.—During the week ending at noon, Wednesday, January 17th, there were two deaths from small-pox in Boston. No new cases were reported. There are now eleven patients in the hospital on Canterbury Street.

SMALL-POX IN LOWELL.—There was another death from small-pox in Lowell, Mass., this week, making the third death from the disease this year.

DEATH AT AN ADVANCED AGE.—Mr. Edward Ryan, the oldest resident of Newton, Mass., died January 11th, aged nearly one hundred and ten years. He was the father of sixteen children; the oldest one now alive, being the third of the sixteen, is seventy-one years old.

A GIFT TO THE PORTSMOUTH HOSPITAL.—Mr. George Bilbruck has given the trustees of the Cottage Hospital at Portsmouth, N. H., ten thousand dollars for a new hospital building fund.

INFLUENZA IN PITTSBURG, N. H.—A severe epidemic of influenza is prevalent at Pittsburg, N. H., nearly the whole adult population being ill. There have been twelve deaths in this and the neighboring town within the last few days.

AN ESCAPE FROM AN INSANE ASYLUM.—Two inmates of the State asylum for the insane at Cranston, R. I., made their escape last week after smothering the keeper with a blanket and locking him in an empty room. After the keeper was rescued he was discharged for neglect of duty.

VACCINATION: A STUDY IN BLACK AND WHITE.—A physician in Boston who has been vaccinating the employees of some of the large hotels, reports that he was able to vaccinate forty-eight white persons an hour, but only thirty-eight negroes in the same time. As all

the other conditions were the same, the greater thickness of the black man's skin suggested itself as the explanation.

NEW YORK.

THE GOVERNOR'S ANNUAL MESSAGE.—The annual message of the Governor, submitted to the Legislature January 2d, contains considerable matter of interest to the medical profession. In regard to the preservation of the Adirondack forests, the Governor says: "The year just ended has marked a new era in the State in the matter of forest preservation. A new policy has been established, whose good results are already far beyond expectation." During the year a large extent of territory, valued at a million dollars, was added to the State Preserves, not only without expense to the State, but with an actual profit in money sufficient to pay the expenses of the bureau. Such a demonstration of the immediate money advantage of the tax-payer from preserving forest land, to say nothing of the climatic, meteorological and æsthetic gain, ought to be an incentive to the people of other States to continue such good work.

PUBLIC HEALTH.—On the subject of the public health the Governor says: "The spread of cholera in Western Europe last spring called for extra work on the part of the State Board of Health to prepare for the reception of the disease, should invasion take place. Local boards of health throughout the State are required to report upon the sanitary condition of their municipalities, and as to what arrangements had been made to care for cases of cholera, if any came. In order to assure active and efficient work, six inspectors were appointed by the State Board to visit all places of entry into the State, and such other places as would be exposed, reporting the needs for further sanitation, erection of hospitals, disinfecting stations or such like matters of importance to the public health. The wisdom of this work has been well shown in greater energy on the part of local health authorities; and while it is a matter of congratulation that cholera did not reach this side of the Atlantic, had it done so, the readiness in which the most exposed places were put was an assurance that an extended epidemic would have been prevented. The precautions at the Quarantine Station in New York Harbor were equally vigilant and thorough."

CARE OF THE INSANE.—Much space is devoted in the message to the matter of State care of the insane. In regard to this the Governor says, in part: "One of the inevitable results of the new system of State care was that the Central State Board should be endowed with reasonably broad powers of supervision and regulation. It was inevitable also that the creation of such a central board with broad powers should lead to more or less conflict between it and the local boards of managers which were established for each hospital, and whose official life, in most cases, considerably antedated that of the State Commission. That conflict was quite marked and spirited immedi-

ately after the adoption of the State Care Act, but subsequently subsided after the courts had upheld the powers assumed by the Commission. It has arisen again, however, within the last two months, and there seems to exist to-day anything but a cordial feeling of co-operation between the State Commission in Lunacy and the local boards of hospital managers. . . . I have endeavored, by bringing local managers together with the State Commissioners, to ascertain where the causes for grievances lay, and to bring about their correction so far as the administration of the law was at fault. These conferences have disproven many published allegations, and I am confident that as soon as the new system is fully understood it will prove satisfactory to the people. At the same time, the existence of the local boards of managers will serve a useful purpose in checking any arbitrary tendencies on the part of the State Commission. Certainly, in carrying on so noble a State charity, there should be no unnecessary friction among public officers. Neither personal nor political considerations should find any place in the discharge of this official obligation. For this reason, we should not only establish sufficient safeguards around the administration of the law, but encourage harmonious enforcement of its provisions by administrative officers."

TUBERCULOSIS IN CATTLE.—This subject is thus spoken of: "The examination of cattle for tuberculosis has been steadily pushed. In all, since January 1, 1893, 19,001 head have been examined, and 618 killed to prevent the spread of the disease. Microscopical and bacteriological examinations have been made of milk and specimens made *post-mortem*, showing the presence of the tuberculosis germ in all. Care is exercised in the examinations, and careful records are kept. The result will be, if work in this direction is continued, to improve the cattle in the State, enhance the dairy interest, and add a further protection to the public health by removing this source of disease germs."

A DISLOCATED AND FRACTURED NECK.—There is at present at the Gouverneur Hospital, a lad nine years of age, who was knocked down by a truck on January 10th, and suffered a dislocation and fracture of the cervical vertebræ. The dislocation was set, and the patient placed in a plaster-of-Paris dressing. As the fracture was slight and the spinal-cord apparently uninjured, he seems to be in a fair way of recovery. Since the apparatus was applied he has been gradually improving. His mind is perfectly intelligent and there is no paralysis of motion; but he does not articulate very well, and his respiration is somewhat labored and irregular.

DR. STODDARD'S APPOINTMENT TO THE STATE BOARD OF CHARITIES.—Governor Flower has nominated Dr. Enoch V. Stoddard, of Rochester, as a member of the State Board of Charities, to fill the vacancy caused by the death of Mr. Oscar Craig, and the nomination has been confirmed by the Senate. Dr. Stoddard was born in Connecticut in 1840, and was gradu-

ated from Trinity College. For two years he was at the Yale Medical School, and then completed his studies at the Albany Medical College, from which he received the degree of M.D. in 1868. In the same year he was commissioned a surgeon of volunteers by Governor Seymour, and went to the front with the 65th New York Regiment. Immediately after the close of the war Dr. Stoddard commenced the practice of his profession in Rochester, and for many years he has been on the staff of the City Hospital there. In 1873 he was appointed to the chair of Therapeutics and Hygiene in the Buffalo Medical College, and in 1892 was made Professor Emeritus.

Miscellany.

ELEVENTH INTERNATIONAL MEDICAL CONGRESS.

A LETTER directed to Dr. A. Jacobi by the Secretary-General of the Eleventh International Medical Congress, and dated December 19, 1893, contains the following communications:

American members will pay on the English, French and Italian railways single fares for double journeys, and will obtain a reduction of twenty per cent. on fares for Italian round-trip tickets.

"The documents required for their identification will be sent to you in January, and Americans intending to visit the Congress will have to apply to you for them.

"Full particulars concerning the journeys will accompany the documents.

"Messrs. Thos. Cook & Son, London, Paris, Rome and Naples, should be applied to for accommodation and for tickets for the excursion at Rome, Naples, and to Sicily. Such excursions will be arranged at Rome under the guidance of Mr. Forbes, member of several scientific societies and correspondent of the *Times*—for Naples, three days, including Vesuvius, Pompeii, Capri, Sorrento, Castellamare, Bajæ, etc.—for Sicily, ten days from Naples, including Messina, Taormina, Catania, Girgenti, Siracusa, Palermo, and return to Naples.

"The fares for members of the Congress will be considerably reduced and comprise hotel accommodations, carriages, guides, boats, etc.—about 70 francs each, for the three days, and 285 francs for the ten days.

"Full particulars concerning these excursions will be contained in a leaflet to be added to the instructions and documents for the journey."

Only the North German Lloyd (22 Bowling Green) and the Compagnie Générale Transatlantique (3 Bowling Green) have thought fit to grant any reductions to Congressists.

FOOT-BALL VS. INSURANCE.

In a recent editorial in the *New York Medical Examiner*, Dr. G. W. Wells speaks of the bearing of foot-ball upon the insurance of a player. The subject of athletics is one which every insurance company considers in a very practical way. As underwriters,

they are obliged to look upon foot-ball as upon any other occupation; that is, in the light of danger to life or health, or as a cause of shortening the normal longevity of man.

There are in the game three classes of casualties: namely, those which are fatal, either immediately or shortly after; second, those from which recovery takes place sooner or later, with or without deformity; and third, those from which recovery never takes place, but ever after the victim carries with him results or reminders, either physical or mental, which place him in the category of chronic invalids.

If he is a policy-holder, and engages in this dangerous game, as now presented, he is putting his company to an extra hazard, for he is in immediate and constant danger of death; and his insurance may become a claim, by death, at any moment during the season.

In view of the many insidious and secondary affections resulting from foot-ball, of which he gives a most appalling list, Dr. Wells considers that a history of having played foot-ball should cause a more rigid scrutiny of the applicant for insurance by the examiner than in ordinary cases. In spite of this view that foot-ball and athletics are liable to render the applicant a questionable subject for insurance, we can but think that the members of our foot-ball and athletic teams are about as healthy and promising specimens of young manhood as are often seen, and that, save for social reasons, they stand in less need of insurance than any other class of men.

SELF-MUTILATION IN CHINA.

THE *Medical Press* gives the following account of a curious custom which only the ancestral worship of China could account for:

"The dearest hope known to an elderly Chinaman is to have descendants, and the main reason of this appears to be that when he comes to die his last days may be cheered by the conviction that he has left a goodly following of his own flesh and blood to worship, as the custom is in China, at his grave. But even the calculations of the "Heathen Chinee" are, in this respect, sometimes prone to be woefully thrown out of gear by a concatenation of circumstances, the occurrence of which could not have been foreseen. Of course, the Chinese father relies on his sons to propagate the race, and when there is only one son left upon whom this responsible duty devolves, it is obvious that much should be made of him. Facts go to show that sons are fully aware of the important position which in this particular they fill in the domestic circle, and consequently they expect and demand a full measure of consideration and regard from their male progenitors. Should it happen, however, that any serious quarrel arises between father and son, the son has it within his power to revenge himself to an extent which is absolutely unknown in more civilized communities. Probably no one but a Chinaman could understand the anguish of a Celestial father who suddenly learned one day that his only son had by one swoop of a razor relieved himself of his penis and testicles! But this is the mode of retaliation which aggrieved Chinese sons adopt towards fathers who offend them. Dr. Robert Coltman, of Peking, has just recorded two cases in which, for the reason mentioned, the sons made a clean sweep of their generative organs.

A SANITARY SERMON IN DIAGRAM.

DR. JOHN C. SUNDBERG, the United States Consul at Bagdad, has sent to the *Pacific Medical Journal* so telling a sketch of the sanitary condition of the water-supply of Bagdad that it is worthy of reproduction. It needs no comment.

1. United States Consulate. 2. Board of Health. 3. A house built out in the river, the wall of which stops dead cats and dogs, human faeces, etc., floating down. 4. Place where the water-carriers take the water which we have to drink. 5. Women and men washing clothes, rugs, etc., stained with cholera dejecta. 6. A row of men defecating in the water and washing their ani, also urinating. 7. Dead buffaloes, horses, dogs, cats, etc., floating down the river. 8. Water-carriers' donkeys always urinating and defecating while waiting for their loads.

PATHOLOGY AND THE SCIENTIFIC MIND.

In his introductory lecture at the Medical College for Women, Dr. William Russell¹ spoke of the development of our knowledge of pathology and the evolution of the scientific mind to its present ideal.

The most primitive idea of pathology was simple and spiritual enough. Disease and sickness were the work of evil spirits who, by the initiated, could be exorcised by charms and ceremonies. Prevention and exemption from disease might be sought for in a devil-worship. An advance upon this was the attributing of disease to a spirit, not normally evil, but beneficent; disease being the manifestation of his righteous anger, relief was sought not by propitiation but by sacrifice. The Hebrew idea was but a modification of this in the monotheistic belief of special revelation and punishment. The speculative character of the Greeks led to a different order of things, with them it became the province of philosophy to explain the ever visible phenomena of disease and death. There were hot, cold and moist hypotheses — doctrines of one cause. From this speculative chaos light arose when Hippocrates separated medicine from philosophy, and began crudely and falteringly to make medicine a science of observation instead of speculation. It was this that gave to him the fatherhood of modern medicine.

No material advance was possible until the structure of the body was followed and its various functions more or less defined. As knowledge of these was being acquired, as new facts were discovered, and new light was thrown upon the working of the complex animal organism, their bearing upon diseased processes

led necessarily to controversies and contentions, and there were solidistic and humoral schools of pathology, there were beliefs in spontaneous generations, in epidemic constitutions, and so on, all of them indicating and proof of the uncertainty of knowledge and its incompleteness. However, the bounds of reliable knowledge gradually extended. Following upon assured knowledge of normal structure came the recognition of abnormal structure in the various parts and organs of the body.

This progress has gone on till such "is the state of our certain knowledge of visible processes, that in the great preponderance of instances there is no room for differences of opinion amongst experts. Cases, however, remain in which from incomplete knowledge there is still room for differences of view as to the interpretation of appearances; as to appearances themselves there is practically none. But even here it is necessary for the truly scientific mind to candidly and frankly dissociate appearances and their interpretation. Interpretation is sometimes a matter of provisional judgment or opinion, and often must and ought to remain so until knowledge is so complete that doubt can no longer exist. And it is this candid open-mindedness which is, I take it, the ideal scientific spirit towards which we have all to work."

The aim of medical training is the development of a well balanced judicial mind upon assured knowledge and accurate observation. The unimpassioned search for truth is the highest conception.

Correspondence.

[Special Correspondence.]

LETTER FROM PRAGUE.

THE STUDY OF PATHOLOGY IN PRAGUE.

PRAGUE, December 17, 1893.

MR. EDITOR: — The conditions for the study of pathology are better here in Prague, so far as I can learn, than anywhere else in Europe. The number of autopsies is very large, and the material is well worked up from every point of view. Anatomy, histology, embryology and bacteriology enter constantly into the daily work, and my respect for each of these branches of medical science is rapidly increasing. The view of pathology taken is very broad, and the ideal taught by example is one not easy to attain. The study of pathology is centred in the Pathological Institute, a large building in the suburbs of the city on Krankehausgasse. In close proximity to it, on the same street, are the General Hospital, the Anatomical Institute and the Chemical Laboratory. The post-mortem examinations for most of the hospitals in the city are made at the Pathological Institute between the hours of eight and eleven in the forenoon. The *Secir-Halle*, or autopsy-hall, is a large room on the first floor, and is furnished with three marble autopsy-tables. On the same floor are three large rooms for the assistants, one for the demonstrators, a room for medico-legal autopsies, the lecture-room, a chapel, macerating-room, etc.

The present Professor of Pathology is Hans Chiari, who was called here from Vienna ten years ago. In his department are three assistants, two demonstrators and several volunteers. The autopsies at the Pathological Institute and at the hospitals are divided equally among the three assistants. Chiari makes only those autopsies which are of especial importance, and also what are called clinical autopsies. These latter are made by special request before a visiting physician or surgeon and his class in interesting cases, and they take place, as a rule, several times a week.

¹ Edinburgh Medical Journal, January, 1894.

By eleven o'clock the autopsy-room must be in perfect order, the bodies removed and the tables cleaned. Chiari first reviews the diagnoses of the previous day, corrects mistakes present, and adds any bacteriological or microscopical notes that may be ready. Then each assistant demonstrates the organs from the various autopsies which he has made, and Chiari advises, corrects, commends or reproves as necessity demands. All the diagnoses must be given in correct Latin. After the organs have been looked over and arranged for the demonstration, the two demonstrators show first the fresh tumors which have been received, and later slide-preparations of the tumors which have already been hardened; descriptions of the appearances are entered in the histological protocoll, and the reports of the completed cases are filled out for the surgeons. In the protocoll, opposite each tumor is entered the name of the demonstrator or special student who has taken it for examination, so that if a report lags the one to blame is easily traced. Every day in the week, from quarter-past twelve to one, a lecture on pathology is given in the lecture-room across the hall from the autopsy-room. As a lecturer Chiari is delightful; he speaks without notes, clearly, distinctly and rather rapidly; his subject is perfectly arranged in his own mind; and he never hesitates in the expression of his thoughts or for the lack of the appropriate word. His lectures are illustrated naturally and easily by numerous blackboard sketches and by many beautiful and appropriate specimens from the Pathological Museum. He calls his lectures *demonstrative lectures*. Immediately after the lecture comes the demonstration of the fresh pathological specimens in the autopsy-rooms, by Chiari at one table and by one or more of the assistants at the other tables. Three times a week an autopsy is made by students during the demonstration, under the supervision of an assistant. Microscopical sections illustrative of the subject of the lectures are also shown at the time by the demonstrators.

The medico-legal autopsies are made in a room adjoining the autopsy-hall by Professor Dittrich, until lately Chiari's chief assistant; and the material obtained is also used at the demonstrations.

The following table will show the number of autopsies made each year for the last seven years:

Year.	Pathological Institute.	Children's Hospital.	Other Hospitals.	Total.
1886	824	144	75	1,043
1887	790	152	68	1,010
1888	857	212	46	1,115
1889	773	186	44	1,003
1890	882	209	23	1,114
1891	843	175	102	1,120
1892	841	157	74	1,072

The Children's Hospital is but two blocks away, and has a large autopsy-room furnished with everything needful, as have also the other hospitals at which autopsies are made. Infectious diseases furnish a large part of the pathological material, and include small-pox, influenza, scarlet fever and diphtheria.

The room for pathological histology is on the second floor, over the autopsy-hall. The class meets twice a week from five to seven P. M., doing all work by lamplight, as it is the only spare time left in the day. A student can take the course only after having heard first the lectures on pathology. Six specimens are given the class each time; and towards the close of the exercise Chiari gives a talk concerning what they have been studying. Smoking is indulged in by every one during the exercise. The class usually numbers from forty to fifty men.

The lectures on pathology are heard by about one hundred men in the course of the year; and, in spite of six

lectures a week, the field of special pathology is never completely covered.

The Pathological Museum is in a large hall on the second floor, and contains over six thousand rare and valuable specimens, all carefully arranged and catalogued. On the same floor are the professor's private rooms, library, and also his home.

The assistants are also lodged in the Pathological Institute, and receive a salary of 600 guildens (\$240) a year. An effort is now on foot to increase the salary to 900 guildens. Internes in the hospitals receive the same remuneration.

The examination in pathology consists of two parts, practical and theoretical, and can be taken only after a student has attended the university for five years. Any time after that, when he thinks he is properly prepared, he can apply for his examination. Besides attending the lectures and the course in pathological histology, it is customary for each candidate for examination to take three or four weeks' drill under an assistant in performing autopsies and in examining microscopical specimens. The practical examination or *rigorosum* lasts about half an hour. I have attended several of them, and found them very instructive. Usually the candidates come in groups of two or three. One is requested to describe the external appearance of the body, and to make a part or even the whole of an autopsy, demonstrating the lesions found. Another removes the brain, and later is required to demonstrate part of the organs from another autopsy. Each man must do enough to show what he knows. Immediately after the examination of gross material each candidate is given a hardened pathological specimen, from which he cuts razor sections, stains, mounts and makes a diagnosis. On the same day, but usually at some later date, comes the theoretical examination, a fifteen minutes' quiz on a variety of subjects in pathology. The examinations are public, and the dean and one other official are usually present.

Besides the autopsies, the assistants have certain other duties portioned out to them: the first assists at the demonstration, and, with the second, has charge of the bacteriological department. The second assistant looks after the instruments and the museum preparations. The third has charge of the histological course, the protocolls and the microscopes. They are appointed from the demonstrators, two in number, who make microscopical preparations of the various tumors, etc., and have numerous other duties. The demonstrators are selected from the volunteers, of whom there are usually half-a-dozen in the laboratory, those having the preference who have worked in the anatomical or other laboratories. It will thus be seen that each assistant has worked up to his position, and is well trained in the various kinds of laboratory work.

The position of assistant in the Pathological Institute is greatly sought for, for the reason that it is a great stepping-stone to the position of interne in the hospitals. Here a clinical professor chooses his own interne, who not infrequently holds his position for two, four and even for ten years. The fact that the university and the hospitals are State institutions has certain great advantages. A clinical professor in the university receives a certain clinic in the hospital, which is henceforth known by his name; and his instruction is continuous, a matter of great importance to the student. The bodies of all who die in the hospitals come to autopsy, so that the pathological lesions in each case are known, and the diagnosis previously made is verified or corrected. At home, clinical instruction is interrupted by change of service, and autopsies are few, and rarely obtained in the most interesting and doubtful cases, over which, perhaps, much time and study have been spent.

A special student in any of the various branches of medicine could hardly find a better place for the study of the pathological side of his subject than in Prague. The number of autopsies is very large, and the material interesting and varied, for the reason that chronic tubercular cases are for the most part excluded. The museum contains not only many rare cases, but also the best specimens of all the more ordinary forms of disease. The number of

special students is constantly varying; at present there are three, of whom two are Russians. Chiari devotes considerable time nearly every day during the forenoon to his special students, who are taught to work in a systematic manner, and to make sketches and drawings with notes of their various preparations. His reception of strangers is most cordial; and he treats them all as fellow-workers with himself in the great field of pathology.

The bacteriological department is in two large rooms on the ground-floor, and is well fitted up with the necessary apparatus and with abundant culture media.

Briefly stated, the advantages for the study of pathology in Prague are the following:

The abundance and the variety of the pathological material, including all the acute infectious diseases.

A large museum stored with rare and valuable specimens from previous autopsies and from operations.

A large collection of histological material from various cases.

The personal supervision and instruction from the professor of pathology.

The concentration of the autopsies, bacteriological and microscopical work, museum, library and protocols within the same building, and all under the direction and immediate control of one person.

The perfect order and system preserved in every department, from the autopsy-room to the museum, and required of every person working in the laboratory.

Very truly yours,

F. B. MALLORY, M.D.

MODERN REALISM AND ZOLAISM IN SPANISH LITERATURE.

MR. EDITOR:—The following passages are *literal* translations from a modern Spanish society novel, and may be interesting from a medical point of view in that they show to what source the present school of writers of fiction in Spain is compelled to resort for matter interesting (?) to the general public:

"All, all had she suffered with resignation up to that moment; the auscultations, the palpations — which she considered shameful — of the accoucheur; the explorations to which she submitted her denuded body and enormous belly, in the lateral or dorsal decubitus, in order that this unknown man might examine the sides or fundus of the uterus — as he said — that he might profane her body! — as she felt assured; — the stethoscope constantly fixed upon her abdomen in order to perceive and count the fetal heart; the spiderlike tickling in the innermost parts of her belly, so persistent and annoying that it produced spasms, a species of incessant convulsions; the vomitings, the bulkiness, the monstrous tumefaction of the breasts, with pains so acute that they made her cry to heaven; the unwieldiness of her belly, rounded, fluctuating, convex, really incommensurable, which impeded the liberty of her movements; the insupportable tremblings of the fetus in its prison, at times more constant and brusque; the varicose and oedematous condition of her lower limbs and of her vulva, which made her think of death with pleasure; the vaginal granulations so profuse that they had made of her parts a deposit of pus rather than the external genitals of a woman; . . . the leucorrhoeal flow, abundant, viscid, trickling down her thighs, staining the sheets." . . .

"Rafaela was a case of rickets, or, better said, of osteomalacia; he knew, because it was plainly evident, that the primipara had no hips, that she must, consequently, have a narrow and deformed pelvis; and he knew, from a consideration of the preliminary phenomena of pregnancy, the suppression of the menses, the vomitings, the swelling of the breasts, the prominence of the nipples, the deep and accentuated coloration of the central areolæ and the increasing extension of the mottled areolæ, the evacuations of milk, the disappearance of the umbilical depression, the albumen in the urine, the vaginal granulations, the leucorrhoeal flow, and in general the whole symptomatology of pregnancy; he knew that failure to bring about abortion at a certain time, and the sooner the better, before the sixth month, condemned Rafaela to death." . . .

"She had stained the counterpane of the bed with green vomitus; and as her whole body was one convulsion, from head to foot, and the vomiting never ceased, that room was transformed by her into a sewer so full of viscidities of every sort that they almost reached to the doctor's ankles." . . .

"But the good doctor from the house of succor had reckoned without his host; the host in this case was Doctor Nieto, who by his delay in operating, by his citations, and his 'distinguo's' had caused the parturient grave injuries, such as beginning rupture of the uterus and of the bladder, inflammation of the peritoneum, and an adynamic and febrile state, very evident from the mental confusion of Rafaela. Moreover, the time which he had allowed to pass without performing the operation, and the force with which the fetal head had been compressing the parts below the straits and of the excavation, had produced in Rafaela violent contusions, which might be the origin of gangrene; and as a result of it, the formation of vesico-vaginal and utero-vaginal fistulae, of a separation of the symphysis pubis, and as a probable result of this, the determination of exhausting inflammations and suppurations and perchance as well of a great mobility of the articulations of the pelvis; . . . or what is the same, in clearer terms: of the impossibility to walk or stand." . . .

"He made use, this doctor, the saviour, with the dexterity acquired by the hand of a man who is guided by great conscientiousness, he made use, in order to accomplish his bloody operation, of a system which merits the term 'double'; a system made up of the series of operations which together receive in obstetrical science the name of craniotomy — perforation of the skull by means of Smellie's scissors; — extraction of the cerebral substance and crushing of the base of the skull by the cephalotribe — and of decollation by Lee's method; moreover he amputated the fetal arms, perforated the chest and abdomen, and, finally, introduced the blunt hook into the pelvis of Rafaela, making traction on it, once it was well fixed, with force sufficient to extract the distorted creature." . . .

What a delicate and beautiful picture of the process of pregnancy and parturition to place within the reach of the modern Spanish woman under the guise of a society novel!

Very truly yours,

J. W. COURTNEY, M.D.

ROXBURY, January 12th.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JANUARY 6, 1894.

Deaths reported 2,387: under five years of age 941; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 325,

acute lung diseases 665, consumption 344, diphtheria and croup 173, scarlet fever 35, typhoid fever 23, diarrhoeal diseases 24, measles 23, whooping-cough 22, cerebro-spinal meningitis 11, erysipelas 5, malarial fever 2, small-pox (New York) 2.

From diarrhoeal diseases New York, Philadelphia and Fall River 5 each, Brooklyn 4, Milwaukee and Lowell 2 each, Boston 1. From measles New York 13, Philadelphia, Brooklyn, Cleveland, Milwaukee and Fall River 1 each. From whooping-cough New York 9, Philadelphia 5, Milwaukee 3, Brooklyn 2, Boston, Cincinnati and Woburn 1 each. From cerebro-spinal meningitis New York 4, Lowell 2, Brooklyn, Cleveland, Worcester, Somerville and Chelsea 1 each. From erysipelas New York 3, Brooklyn and Cleveland 1 each. From malarial fever New York and Brooklyn 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending December 23d, the death-rate was 24.7. Deaths reported 4,896: acute diseases of the respiratory organs (London) 635, whooping-cough 149, diphtheria 82, measles 81, fever 70, scarlet fever 63, diarrhoea 34, small-pox (Birmingham 4, West Ham 2, London and Liverpool 1 each) 8.

The death-rates ranged from 13.5 in Blackburn to 41.5 in Plymouth; Birmingham 26.8, Bradford 18.6, Bristol 33.6, Croydon 23.0, Hull 24.2, Leeds 17.5, Leicester 22.6, Liverpool 31.6, London 26.3, Manchester 22.8, Newcastle-on-Tyne 19.1, Nottingham 24.4, Sheffield 23.9, West Ham 19.3, Wolverhampton 35.3.

METEOROLOGICAL RECORD.

For the week ending January 6, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 6, 1894, TO JANUARY 12, 1894.

The extension of leave of absence granted CAPTAIN CHARLES E. WOODRUFF, assistant surgeon, U. S. A., is further extended one month and twelve days.

Leave of absence for two months, on surgeon's certificate of disability, with permission to leave the Department of Dakota, is granted FIRST-LIEUT. CHARLES F. KIELLER, assistant surgeon, U. S. A.

FIRST-LIEUT. EDWARD L. MUNSON, assistant surgeon, U. S. A., is relieved from duty at Jefferson Barracks, Missouri, and will report in person to the commanding officer, Fort Assiniboine, Montana, for duty at that post.

AN ARMY MEDICAL BOARD.

An Army Medical Board will be in session at Washington, D. C., during April, 1894, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before March 15, 1894, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character and habits. The candidate must be between twenty-two and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the Board.

Successful candidates at the coming examination will be given a course of instruction at the next session of the Army Medical School, beginning in November, 1894.

Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday evening, January 24th, at 8 o'clock, by Dr. Edward Cowles. Subject, "Mental Physiology." Physicians are cordially invited.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held at the Medical Library, No. 19 Boylston Place, on Monday, January 22, 1894, at 8 o'clock, P. M.

Dr. H. C. Baldwin: "Two Cases of Syphilitic Origin; Meningitis and Progressive Muscular Atrophy." Discussion by Drs. M. Prince, G. L. Walton and others.

Dr. F. W. Gosw: "Two Cases of Pulmonary Congestion and Oedema Occurring during Pregnancy." Discussion by Drs. E. Reynolds, C. M. Green and others.

Dr. E. G. Brackett: "The Use of Gymnastics in the Treatment of Lateral Curvature." Discussion opened by Dr. E. H. Bradford. Drs. E. M. Hartwell and C. Enebuske have been invited to be present and to take part in the discussion.

Members are kindly requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., Secretary.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, on Wednesday evening, January 24, 1894, at 8 o'clock.

Dr. E. H. Stevens, of Cambridge, will read a paper on, "Twelve Cases of Obstetrical Septicemia Seen in Consultation." Discussion by Drs. W. T. Councilman, C. M. Green, M. H. Richardson and C. W. Townsend.

Dr. H. C. Baldwin: "Three Cases of Retroversion." EDWARD REYNOLDS, M.D., Chairman. GEO. H. WASHBURN, M.D., Secretary.

APPOINTMENTS.

The managers of the Boston Dispensary have made the following appointments: HORACE D. ARNOLD, M.D., assistant in the orthopedic department; JOSEPH C. STEDMAN, M.D., assistant in the department for diseases of the rectum and anus; and F. E. TOWNE, M.D., and FARRAR COBB, M.D., district physicians.

RECENT DEATH.

CHARLES GILMAN SMITH, M.D., died in Chicago, Ill., January 10th, aged sixty-five years. He graduated from Harvard College in the class of 1847 and from the medical school of the University of Pennsylvania in 1851.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the American Ophthalmological Society, Twenty-ninth Annual Meeting, New London, Conn., 1893. Hartford: Published by the Society. 1893.

Twenty-third Annual Report of the Bureau of Statistics of Labor, March, 1893. The Annual Statistics of Manufactures, 1892. Boston: Wright & Potter Printing Co., State Printers. 1893.

Essentials of Practice of Medicine. By Henry Morris, M.D. And an Appendix on Urine Examination. Illustrated. By Lawrence Wolff, M.D. Third edition, enlarged by some three hundred essential formulae, selected from eminent authorities. by Wm. M. Powell, M.D. Philadelphia: W. B. Saunders. 1894.

The Art of Living in Australia. By Philip E. Musket, Late Surgeon to the Sidney Hospital; Formerly Surgeon Superintendent to the New South Wales Government; Medical Superintendent, Quarantine Station, Sidney, and Senior Resident Medical Officer, Sidney Hospital. London, Edinburgh, Glasgow, Melbourne, Sidney and New York: Eyre & Spottiswoode, Her Majesty's Printers.

An American Text-book of Gynecology, Medical and Surgical, for the use of Students and Practitioners. By Henry T. Byford, M.D., John M. Baldy, M.D., Edwin Cragin, M.D., J. H. Etheridge, M.D., William Goodell, M.D., Howard A. Kelly, M.D., Florian Krug, M.D., E. E. Montgomery, M.D., William R. Fryer, M.D., George M. Tuttle, M.D. Edited by J. M. Baldy, M.D. With 360 illustrations in text and 37 colored and half-tone plates. Philadelphia: W. B. Saunders. 1894.

Lecture.

LECTURES ON SURGERY.¹

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XXIII.

HIP DISEASE. — POTT'S DISEASE.

YOU must conceive, of course, that these lectures are mere outlines; and when you see the large books that have been written upon these special deformities, and reflect how much the student has got to carry in order to learn all that is known on any given subject, it seems to be rather discouraging; but our business is merely to mass together certain facts, to draw outlines, so to speak, which you can fill in afterwards; and, therefore, if a great many details are omitted, you must expect that you can only get the principal things firmly fixed in your minds, and that is all that I attempt to do.

In speaking of hip disease, I said that the earlier symptoms of the disease were the slight limp, eversion of the foot, apparent elongation of the limb, and that, soon after, this gave place to more marked lameness, drawing in of the foot, evidently inversion of the limb with decided shortening, this marking the completed stage of the disease. In the earlier stage of the disease the diseased condition begins in the synovial sac, or it begins in the head of the bone. In one case it proceeds to the pulpy degeneration of the synovial membrane, ulcerating the cartilage and finally affecting the bone; and in the other case it starts as cheesy, tubercular deposit in the head of the femur, destroys the cartilage by its contact with the disease and the cutting off of its nutrition, invades the joint, converts it into an abscess, bursts through the joint, and finally ends in dislocation of the bone. The child, at first a little lame, now becomes a great deal more lame, and shrieks out with pain at night. After a period of great feverish excitement, a space of time follows in which there is entire relief, and the child seems better. This coincides with the bursting of the abscess through the capsule of the joint, getting rid of the tension and relieving the extreme symptoms of pain and fever. Subsequently to this inversion and shortening of the limb, another period of fever comes on, marked by the progress of the abscess into the cellular tissue, finally breaking through a small opening through the skin, and this again followed by a period of relief. The shortening and inversion which take place at this period are due to dislocation of the head of the femur, which occurs as perfectly on the dorsum of the ilium as if it were in consequence of violence. In other words, the ligaments have given way, the joint being disorganized, synovial sac ruptured, the head is pulled out from the socket, thrown out on the dorsum by the powerful action of the muscles, and shortening of one and a half to two and a half inches, with inversion of the limb, takes place.

Subsequently to this, nature pursues one or two courses, usually the latter. The first course would be to try to establish a new and false joint on a new part of the bone, the head resting on the dorsum. The other and more common termination is to establish

ankylosis — absolute bony ankylosis between the diseased and wasting head of the femur and the false socket, surrounded with osteophytic growths, on the dorsum of the ilium. This is the usual termination. The child who goes through all the stages of the disease from the first synovial inflammation ends with ankylosis, with the head of the femur against the dorsum of the ilium in the characteristic position of dislocation of the thigh upon the dorsum of the ilium. Sometimes, in fortunate cases, this is all the deformity that ensues; but in many other cases, on account of entire neglect of treatment in keeping the limb in the proper position while these changes are taking place, the patient yields to the natural impulse to relieve suffering by drawing up the leg. The leg, then, is not only shortened by the disease, but the knee is drawn up and shortened by the efforts of the patient. In addition to this, powerful adduction takes place, so that, in extreme cases, the deformity is great, the head of the femur being dislocated and the leg shortened, and the knee drawn up nearly in contact with the abdomen. These are the extreme cases of deformity which afterwards result in ankylosis, with a perfectly useless limb; the child walking with crutches upon one foot, and the other foot wasted, and carried high (in the air). This is the natural course of the disease if it pursues all its stages. It does not necessarily, however, pursue all these stages, for sometimes it becomes arrested in its progress, and then, in some very favorable cases, the disease may be made to stop short of dislocation, and in some cases, probably, stops short of real abscess; or if slight abscess exists, it does not become enough to burst the capsule, becomes inspissated and absorbed, and the child gets well. The head of the bone altered somewhat, but still inside the socket, and fastened by fibrous if not bony adhesions. That is in the mild cases.

Inasmuch as treatment, to be effectual to arrest the disease, must be applied at a very early stage, it becomes important to know what are the exact diagnostic signs of this disease when it is first beginning, for it is in the very early stages only that we can do much good.

Lameness, limping and pain moderately marked, usually concealed a good deal by the child. The hollow of the back is very peculiar. The child, laid down on a table, arches the back in such a way that the hand can be readily passed under the small of the back without touching the back. On examining such a child and comparing the two sides, it will be found that the first noticeable change is a loss in the sharp contour of the line of the groin which separates the femur from the abdomen and pelvis; and next to this a wasting of the glutæi muscles, due to disease, and a consequent loss of that sharp fold which marks the division of the lower edge of the glutæi from the posterior femoral group of muscles; in addition to this, an increased prominence of the greater trochanter of the femur. If now the two joints of this child are examined, first the hip of the well side and then of the diseased side, a marked difference will be found. In case of a healthy femur, we may take the femur and rotate it almost as freely as the humerus without eliciting any movement on the part of the child. The moment we touch a diseased limb we have a joint locked by the muscles, firmly held by muscular spasm set up at once by nature the moment we touch the limb in order to avert the chance of suffering from

¹ These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

moving the diseased joints upon each other; and although the child may go about with a moderate amount of motion in these cases, yet the suddenness and completeness with which nature will lock the joint when it is seized and attempted to be moved is a very significant fact. We find a limited motion. We find that the movement which we are making is moving the pelvis as well as the femur; that there is an ankylosis which is false, and which, under ether, is shown to be absolutely false, but which demonstrates the great difference between the diseased and the healthy side. I do not think that this muscular spasm and ankylosis is ever wanting in the well-marked case; and that, together with the loss of the fold in the groin, flattening of the nates, arching of the back and stiffness of the joint, are the very early diagnostic marks of the disease itself. Direct pain by pounding about the joint is not generally elicited, except in the advanced state. Grating or rubbing in the joint itself is almost never elicited unless the patient is not only etherized, but in a very advanced stage of the disease; and even then it is seldom got, for the reason that, although the cartilages give way, and you would think the bony surfaces would be brought in contact, yet nature has protected them with a bed of velvet-like granulations, which cover all the diseased surfaces, and prevent them from rubbing together with a crepitus like that of diseased bone. No motion can be got without ether, and with ether the signs of crepitus are not usually to be found. Of course, when abscess has taken place, when dislocation has taken place, we can hardly mistake the disease for anything else, provided we can eliminate any violent accident or injury, which might have caused the dislocation or the abscess from traumatic reasons.

Given a slow-coming-on disease with these phenomena, it means hip disease, and the child will present other signs of tuberculosis in its system, in its features, in its nails, in the eye-lashes, in the shape of the lip and a wasted condition, which speedily shows a state of chronic scrofulous disease. So much for the symptoms and the diagnosis. If nature is left alone in the favorable case, she produces a cure by ankylosis. If this disease has begun early enough in life, and runs on fast enough to complete its stages before the period of puberty is reached, a cure by ankylosis, with entire healing of the sinuses, and subsequently a strong limb, are frequently the result. If, on the other hand, the disease starts later in life, or does not conclude its three stages by the time puberty has come on, then usually the disease remains permanently; and although partial ankylosis may take place between the femur and the ilium, still sinuses are apt to occur, caries is apt to go on. The sinuses may heal and the patient go on a few years, and then, after some sudden exposure, it breaks out again from the old opening. There is a new discharge of pus, a new attack of pain, and new evidence of disease in the joint. This is especially the case in males after they have received a slight sprain or injury, or exposure to cold, if they have grown up with hip disease imperfectly cured; and, in females, it is quite liable to follow the condition of pregnancy, where, after childbirth, the diseased condition is again lighted up, abscesses reopen, and the old trouble about the joint asserts itself again.

As to the treatment we can employ. It must divide itself into a number of stages. The most effectual in the early stages; the less effectual mode of treatment

in the later stages. In the early stages, the moment these preliminary signs are detected, it is essential at once to obey the voice of nature, which teaches us by the muscular spasm that she is making every effort to keep the joint at absolute rest. That is the first and great essential of the treatment of hip disease. The patient should go to bed and keep still. The bed, with extension, is the first treatment of hip disease as soon as it is suspected; and this should be continued until the nightly cries and pain and such symptoms are gone. Frequently in these early cases six weeks in bed will suffice to overcome all the active inflammatory symptoms. The joint becomes almost like the other. The patient is apparently almost relieved; and when that appears, then we can venture to let them get out of bed, and not before. The moment they get out of bed they must be supported by another form of extension, by a splint; which can be applied in such a way that the patient walks on the perineum. I will not describe the apparatus used for this purpose. In addition to this it is of extreme usefulness to oblige the patient for a while to go on crutches; to put on a high shoe on the sound foot, which forces them to keep the sick foot up in the air. The child can get about in that way freely; with extension kept up, so that the diseased bones do not press and churn upon each other. This mode of treatment must be continued a number of months. When you are convinced that another stage of the cure has arrived, you can venture next to take off the high shoe; keep on the splint, and allow the patient still to go about on crutches, and put weight on the limb. Eventually crutches are discarded and the splint alone used; and finally, after a long while, several years, the patient may be trusted to go without anything; and, if fortunate, you may have succeeded in arresting the disease. All this treatment, provided the disease does not go on to abscess, can be continued without suffering, or interfering with the health of the child. Although we consider it bad policy to put one of these feeble children to bed and shut them away from good air; yet we have got to balance this against the rest and ease and absence of fever we shall produce by extending the limb and keeping the joint still; and the moment the early inflammatory stages are passed, the child can be got up and out of doors, and put in the healthiest possible circumstances. Tonics, of course, should be used to build up the child's health.

When abscess comes on before treatment, or in spite of treatment, extension is badly borne. When abscess is forming, and before it has burst the capsule; when it is reforming and trying to make its way into the cellular tissue; extension produces no relief; but produces terrible pain and has to be abandoned. In such a state we must content ourselves by allowing the patient to lie still in bed; apply soothing applications to the limb; wait for the giving way of the abscess at some point; and try to keep the limb down with a gentle splint into as good a position as we can while these inflammatory changes are taking place. When the abscess has burst, or is evacuated, extension can be again applied. Now is the time when nature is about to pull the bone out of the socket, and the time when extension, if kept up vigorously, may avert this; or diminish the extent to which nature will get the advantage of the bone and draw it up on the dorsum. In these cases where abscess has formed, where dislocation is bound to occur, extension in bed by weight

and pulley becomes of vastly more consequence than before. A good deal of weight should be put on; the parts held as still as possible; perhaps the child held down in bed by some brace or confinement; and if the child does well; if it does not suffer; if its constitution holds out; unquestionably that is the best mode of treatment for some months until the tendency to dislocation has subsided. Then a splint can be used; and the treatment continued, for several years, in the way described. Supposing the disease has gone through all its stages and made spontaneous cure by bony ankylosis with the head in contact with the dorsum of the ilium and the limb in an extremely deformed condition, so that the foot cannot be got to the ground, the legs cannot be separated at all, and the limb is wasted and useless; two alternatives present themselves; one is to saw through, or cut through, this ankylosis, or rather through the neck of the bone below the ankylosis, to draw the limb down into place, keep it there in splints for a considerable length of time and to expect union to take place at the point of section in the limb, in a better position; or in some rare cases we expect a false joint. Probably union in the new position is the most favorable result we can have. The only other alternative in this class of cases, or in cases where the disease is still going on actively with abscess and caries, great shrivelling of the limb and uselessness — the only other alternative is amputation at the hip-joint; which, if the patient survives it, cures it. It takes off this mill-stone which is dragging the patient down. Restoration to health and a fat, strong condition is usually the result. Formerly this could hardly be thought of, on account of the immense mortality of amputating at the hip-joint. Now it may be done with comparative safety by the new method of amputating, where great loss of blood is avoided. The vessels are best secured by the figure-of-8 rubber twist held by an assistant with a firm twist which can be tightened; and the limb is amputated, not by the old French method, but by the slower process of excision; and amputating the remaining portion of the thigh by the circular method. By this mode of operating the child loses very little blood; and if in a sufficiently strong state to stand any operation, will recover promptly and get a useful life afterwards, with a useless limb taken away.

The other point of which I wish to speak is, as to operative interference in the earlier stages of hip disease. That operative interference means either opening abscess, and cutting down and tunnelling out and gouging the diseased bone; or doing a still more marked operation, and endeavoring to excise the head and neck of the femur; endeavoring to scrape the acetabulum, if necessary; and allowing the patient to recover with what is called a false joint. The operation of excision of the head of the femur was formerly much more popular than now. In the first few years I was on duty at the City Hospital I did the operation a great many times and published a good many cases; and thought I obtained, sometimes, very excellent results. More mature experience has proved that these results are not so good as they first were thought to be; and the operation is not to be resorted to, provided the patient can be trusted to make a spontaneous cure. The arguments used in favor of excising were these: that you hastened the progress of cure; took out the diseased portion; gave thorough opening and evacuation of the abscess; and made a more useful

limb and joint. The most useful limb the child with hip disease can have is with a moderately well-placed ankylosis with the femur fastened to the ilium. That once firmly bridged over and solid, no subsequent disease affects it; and it is a strong limb which can be used without fear and without pain. The great deformity which was thought to be unavoidable, in former times, not only from shortening, but from inversion, is now known, as the child grows up, to be largely overcome by subsequent mobility of the ankle and knee, and of the pelvic joints at the sacrum; so that I have seen many of these cases where they were not touched by the surgeon, where the patient could walk very well indeed, and without the inversion which was thought unavoidable. That takes away one of the arguments in favor of excision. If you excise, you get fully as much, if not more, shortening, than if you trust to spontaneous cure with the head of the bone on the dorsum. Excision means two to two and a half inches of shortening always; and the subsequent joint is a loose joint. It is not so reliable. It is flexible, but not so firm; and it is liable to recurrent abscesses, and to continuation of the carious processes in the shaft of the femur. You cannot cut off much without making a useless limb; and there may still exist a tuberculous focus. After excision this may follow; that although you have taken off all the disease of the head of the bone, still there remains a tubercular condition of the acetabulum; which afterwards goes on to disease of the pelvic bones and defeats your object.

In addition to this there is another argument against great operative interference in hip-disease, and against opening up medullary cavities; and that is the chance of rapid dissemination of tubercular material throughout the system from any severe surgical operation. Of course, many children with ordinary hip-disease will die of tubercle in other parts of the body; will have tubercle in the mesenteric glands; in the membranes of the brain, or amyloid degeneration of the liver and kidney; so also they will have it in many cases with excision; and sometimes, to my surprise, it has become developed with such rapidity after excision that it seems as if the operation had started a new process of dissemination throughout the body. It seems to be pretty well conceded that the successful treatment of hip-disease is the mechanical treatment; that the earlier you get at it the better the result; and that operations should be reserved for two classes of cases; that operations to saw the bone and replace the limb in a new position should be reserved for those cases where there is ankylosis with such deformity that the patient cannot walk or stand or use the limb in any direction; and that formal excision should be reserved for cases where there is no prospect of cure by ankylosis, and where you may do something by cutting open the parts freely; scooping out the disease, and subsequently closing the wound.

In operating, you have an immediate mortality which is considerable. I have seen several patients die within the first forty-eight hours after excision; and if you get the most perfect result, you have a swinging joint and no more useful limb than before. There can be hardly any doubt, I think, that while surgery ought to interfere in advanced cases, where the child is dying of hectic and suppuration and caries; and that surgery ought to interfere in cases where the limb is so deformed that the child can neither stand nor

sit; that in other cases it is safer and wiser to follow the dictates of nature and seek her method of cure, which is by ankylosis.

Early diagnosis and early treatment are the best here, as in all acute diseases—in any disease, I do not care what it is. In any acute disease, which is threatening, you accomplish more in the first twenty-four to forty-eight hours than in the subsequent weeks; and in any acute disease of bones and joints, you accomplish more in the first few weeks, than in the subsequent months.

The main thing is to keep the joint at perfect rest; to restore it to its natural functions very slowly indeed, and with extreme care; and subsequently, if dislocation and ankylosis take place, to try to keep the limb in as good a position as possible; and to expect, if these stages can be gone through with before the age of puberty, that we shall get a permanent and spontaneous cure.

POTT'S DISEASE.

The next class of diseases of the joints that we shall take up, are those of the spine; and as we are on the tubercular and suppurative class, I will proceed to that which is called Pott's disease, or caries of the spine.

In the specimens passed around, it will be seen that the disease generally begins between the bodies of the vertebræ, in the intervertebral cartilages; that it is distinctly a joint disease. It may proceed as an ulceration of the cartilage, finally affecting the bodies of the vertebræ, or may begin, occasionally, in the bodies of the vertebræ themselves, as a tubercular deposit, affecting and destroying the cartilage by cutting off its nutrition; then leading to erosion of the bones, and to abscess and the deformity, humpback, which we recognize as characteristic of Pott's disease of the spine. Some authorities have gone so far as to say that caries, or Pott's disease of the spine is the result of injury; that the child gets a fall which injures its back; that the fall produces the disease. On the other hand, most authorities seem to be agreed that a condition existing beforehand of intrinsic delicacy of constitution, call it scrofulous or tuberculous or what you like, is essential to the production of the disease; that it may be precipitated and brought into action by a fall; but that it may arise spontaneously; that it is more likely to arise if the child has a fall than without it; but that the fall is not the one sole cause of the disease. One can hardly look at ordinary strong children in the first period in which they run about, from ten months to three years of age, and see their extraordinary suppleness and activity, and the falls they get, and the injuries they undergo without any permanent result, without thinking that the mass of mankind, who are healthy, at that age are so built and constructed, that ordinary injuries do not produce caries of their spines, or diseases of their hip-joints. On the other hand, in the very delicate child, slight injuries, which are thrown off and shed easily in the healthy one, start up this pre-existing tendency to inflammation of the cartilages between the vertebræ, or in the bone. That, I believe, is the usual history. Delicacy in the child, a slight injury or none at all, the commencement of disease in the cartilages, and caries of the vertebræ following. Unfortunately, in the early stages, this disease is more likely to be overlooked than hip-disease in its early stages. It is only in the very earliest stages of this disease that treatment can arrest

the diseased process; and as time goes on treatment becomes more and more hopeless; and when we interfere in the latter stages we should bear in mind that the cure of nature in this disease is also wholly by ankylosis; ankylosis at the expense of deformity; life at the expense of deformity; health at the expense of deformity; and that a case of advanced Pott's disease of the spine which recovers without deformity, and recovers straight and well, must be very rare—I mean without some deformity. Of course, we have all degrees.

The cartilages ulcerate, the vertebræ break down, their bodies drop together and melt away, the spines are thrown backwards out of position, the body becomes bent forwards, and in this false position nature makes a great effort at repair; throws out new bridges of bone; fastens together two adjoining vertebræ; holds the bones in their new position; and finally makes a cure with a stiff joint, and with deformity. That is the common result if left alone.

The early symptoms of caries of the spine are very insidious. They are so because of the youth and activity of the patients; and also on account of the great natural mobility of the spine, and the fact that pain, or diseased conditions, are disseminated, so to speak, up and down the long column, where one part can compensate, to a considerable degree, for a loss of motion and usefulness in the other part of the spine. This disease comes on generally soon after the child begins to run about and be active; one and a half to two years of age, to three or four years of age, is the common time. It rarely begins after childhood. It may begin in consequence of injury, or in consequence of that active tubercular or scrofulous condition which may be lighted up in the feeble child by the second dentition, at ten to twelve years of age. It rarely begins after puberty. If it does not go through its stages and cure itself before puberty, it never gets well, so far as my experience goes. It usually begins as soon as the child begins to run about and be active, and is overlooked, in this way. The child complains of being tired, and is thought to be merely fretful and capricious, or cross. The child is unwilling to go upstairs; it is unwilling to stoop down and pick up things with any celerity; it complains of constantly having pain in the stomach. This pain is about the præcordia and ensiform cartilage; and is a transmitted pain carried along the nerves between the ribs and to their terminations in the centre of the body in front, and the pain is experienced there, and is really a reflex of a disease of the bodies of the vertebræ and about the intervertebral foramina, from which two or three of these pairs of nerves have made their exit. The abdominal and præcordial pain, pain at the pit of the stomach, is a spinal pain; has nothing to do with the alimentary canal. The child is tired; unwilling to make exertion; complains of stomach-ache; frequently sits down to rest itself; supports itself on chairs and furniture; seeks a position where it can get its elbows on the table. A peculiar stiffness of the gait becomes developed very early; the child walks with care, instead of running with that perfect abandon seen in young children. It squares its shoulders, differently from the ordinary loose gait of the child; and it has a sort of military look in its whole bearing and gait. The scapular muscles are set. The child walks as if it were made of glass; and this is very characteristic, and unlike any other disease.

A stiff back, square shoulders, dislike to stooping, constantly supporting itself, and after a little while spasm of the legs, legs adducted, and a tottering gait. If this child is examined, you will find, probably, in the dorsal or lumbar region, a projection, a slight knuckle projecting beyond its fellows. This, however, may exist without the other symptoms; and when it exists without the other symptoms, it does not mean anything at all. You may take a healthy child, strip it, and stand it up, and if it is not very strong, you will occasionally see one vertebra out beyond the others, and looking as if it must have Pott's disease. You will find on examination that this is a false sign. This false sign is to be diagnosticated in this way. When the projecting knuckle is the result of caries of the vertebræ beginning, it is immovable; can never be thrown out of sight; never be effaced; and always stays, in whatever position the child puts its back. You must take this sign in connection with every other sign; but it is an extremely valuable diagnostic mark. But the weakly child, with a loose, projecting spinous process, retains the suppleness of the back, and if pricked or pinched, hollows the back and draws the projecting spinous process in, out of sight.

There is not much pain in the back in caries of the vertebræ. Very little pain is elicited on pressure. Much more pain is elicited on pressure in ordinary sprains of the back, or in an hysterical or nervous condition of the spine, than in Pott's disease. You may press on this vertebra; you cannot elicit pain or displace it. It is held by the muscles, by the ribs, by the locking of bones, in such a way that the pressure has no effect on the diseased point. There are two modes in which you can elicit pain. One is brutal and dangerous; the other is not. You are instructed by some authorities to crush down the spine, and see if the child will cringe. That is dangerous, because it may produce new crushing of the vertebræ already softened. There is another way; you may take the child, that is, lift the child, with the hands around the ribs, about opposite the seat of disease. The heads of these ribs are crowded in against the diseased vertebræ by this effort, and while no harm is done, a scream is almost always elicited; while it does not hurt a healthy child a particle. I do not attach so much importance, however, to these methods, nor do I advise you to pursue them. You can learn much by the general symptoms, and the fact that the projection will not disappear in the case of Pott's disease, and will otherwise. The spasm of the limbs, tottering gait, irritable bladder, wetting the bed at night frequently, constipation, change in the shape of the arch in front, so that the ribs become turned up, and the child becomes pigeon-breasted, the shoulders sinking more and more; the child ceases to grow in size; the head becomes sunken between the shoulders; one knuckle of the vertebræ becomes three, then becomes five, three prominent and two less so, until the marked and unmistakable hump is apparent in the back. This last sign is much more evident in some parts of the back than in others. In the dorsal region, where the curve is outwards, a prominence will show itself much more quickly, than in the lumbar vertebræ, where the curve is inward. The most marked and characteristic of all are the deformities produced in the cervical vertebræ; not only from the sinking in of the head, but by the great spasm of the muscles of the neck; by the peculiar position in which the child constantly carries

itself, and the deformity. Soon after this, signs of abscess begin to come on, marked by hectic fever and sweats. It is a long while before that abscess shows itself on the surface. It is at a great depth. It is near the centre of the body, in front of the vertebræ. There it seeks an outlet in two ways: either gravitates down and gets into the psoas sheath, and emerges under Poupart's ligament, and makes a psoas abscess: or else pushes directly backwards in the loins, emerges from between or below the ribs, and becomes a lumbar abscess. This abscess is essentially a cold abscess; full of caseous matter, and from broken-down vertebræ. It is extremely slow, a matter of months and years; frequently passes away in the end, after the child recovers by ankylosis, without breaking at all. It is absorbed and inspissated in such a way that the abscess finally disappears. When it does break it is after a long period and by a minute opening, by which nature guards the ingress of air into the sac, and lets the pus trickle from a little valvular hole. The abscess continues to discharge for several years. Meanwhile the deformity of the back goes on to cure; reaches its limit; ceases to press out further; begins to assume a fixed position; grows more and more so from month to month; bony ankylosis takes place; the abscess dries up, and the child has recovered, at the expense of great deformity of the back; of deformity of the chest; with strong arms and shoulders, but weak and wasted legs.

These patients live to old age. They appear to withstand other diseases with great vigor. When they have Pott's disease, they rarely have anything else. They are well and active. Moreover, in all this peculiar class of cases affecting the spine it is noticeable, I think, that mental vigor is greater than the bodily loss; that these children are distinguished by mental acuteness; like the blind, who shut off from one sense, develop all the others; so these children, shut off from locomotion and play, and possibly having some sort of diseased condition of the nervous system at one part, seem to develop a certain precocity of mind in the brain; so that wherever you see a humpback child, you find a bright one, who knows a great deal, and has learned as much by observation, as his fellows learn by education.

What shall be done in the way of treatment? Of course treatment to do any good must be applied at a very early stage; and here, just as in hip disease, we try to keep the part at rest. The treatment must be mechanical. The child at first must be confined upon its back on a frame, or with double extension, in some way, so that ankylosis may take place; or if this is impracticable, the child must be allowed to go about with a spinal support, in such a way as to take off the weight of the shoulders and head from the diseased part; to support the spine on the pelvis, and also to hold the parts at rest. The use of the frame on which the child can be strapped and held temporarily, is, I think, most useful, because this does not necessarily confine the child to bed. It can be taken up, turned about and kept clean, carried out of doors and kept more or less in the open air; while at the same time the spine is kept at a perfect state of rest. On the other hand, if this is not practicable, a good spinal support, and allowing the patient to run about, is probably the best mode of treatment. That gives nature a slight chance; and a slight chance usually suffices; and unless an abscess has taken place, a cure usually results by ankylosis.

As to the treatment of these abscesses themselves. Like all cold abscesses there are four methods of treatment: repeated aspiration; injection of a fluid to promote absorption; incision of the abscess, and fourth, I should say, letting it alone. It may become inspissated. Incise it and you run a great risk of septicæmia unless you can clear out and clean every pocket and scrape the carious bone. Repeated aspirations may be useful, but they inevitably end in a permanent opening through which the needle has been passed, and establishing a sinus, so that you merely anticipate nature a little, and prick an abscess, giving it exit through a valvular hole. These abscesses must be watched. There is no haste about them. They are slow. You can afford to wait. If they are opened, you must wash them out and scrape in so thorough a manner that the development of septic absorption may not take place; and even then death sometimes takes place in forty-eight hours from the shock of opening a large pus cavity. Apparatus, if applied early, will check the disease and hold the bones so that they will get in good position and unite by ankylosis. The cure, to be perfect, must be before puberty. Abscesses must be opened very slowly indeed. Remember, the best mode of treatment is to have the child secured on a frame or splint, and taken out of doors; kept in warm air; somewhere where it is constantly summer, if possible; or under the influence of sea air, and the best hygienic surroundings. It is extraordinary how much better these cases do in sea air, than in the air of the hot, inland country.

LATERAL CURVATURE OF THE SPINE.

This is very common. It is a distortion, but not a disease. There is no caries, there is no affection of the spinal canal. There is a twisting of the vertebrae in various directions on account of the unequal action of the muscles of the back. In consequence of this twisting and distortion, the ribs and sternum also get drawn out of place. One of the first signs which attracts attention is the fact that the shoulders are not even. You know how common this is in young people and in those who are growing rapidly; one shoulder is a little higher than the other, preferably the left. That is due in young subjects, however, frequently to careless attitudes in sitting and studying and writing, etc. But this comes on insidiously, and at the same time the shoulder is drawn up, the hip on the opposite side becomes pushed out, to compensate for it, so that we have a high right shoulder and a prominent left hip, for example. It is especially a disease of females, though not confined to them; probably more in females because they have less active exercises than boys. The curve is double, and when it inclines, for instance, to the right side in the upper portion of the vertebral column, there always is what is called a curve of compensation to the left in the lumbar part of the column, in order to balance the body. These two things always go together. In the early stages the spinal column is flexible and movable, and by throwing the arms and muscles in certain positions, the column can usually be restored to shape. As time goes on, if this trouble is not attended to, it begins to distort the cavity of the thorax very much, so that it becomes one-sided, and the child is also pigeon-breasted, so-called, from the projection of the sternum. In a little while the vertebrae begin to be rotated upon themselves, through the action of the displaced and weakened ligaments and

muscles, and although they are not drawn apart from each other, and although the spinal canal is never infringed upon in a way to make meningitis, the resulting deformity sometimes is incurable. The vertebrae become so far twisted out of shape that it is impossible to restore them.

The diagnosis and treatment both are most important in the earliest stage; and in that early stage the trouble can generally be corrected by the proper use of the muscles. One very useful exercise, which is very simple, is to have the child drilled to carry light weights upon the head. This may be any form of light weight; but a very good way to teach the child to do it is to place a little mat upon the head and set in it a bowl of water; and the child is instructed to walk backwards and forwards so many times. The slightest deviation will cause the tipping of the bowl and the wetting of the neck, and speedily remind the child to resume the upright position. It is a well-known fact, that among the races of the tropics and some parts of the south of Europe, the custom of carrying heavy burdens upon the head leads to an unusually upright and steady form. It is not the custom here in any form of labor; and it is never practised in gymnastic exercises. In addition to this, the child should be watched carefully about sitting, studying and sitting at school; and instructed, if weak, to lie down certain parts of the day in the prone position, on the stomach and chest, and with the arms in such a position as to bring the spine back to its natural curves. These children are weak, and if the spine begins to get out of place, the back muscles grow weak, and the child droops more and more. The other exercises which are more important are gymnastic and calisthenic exercises, which may be done with light weights and wands or dumb-bells and light gymnastic apparatus: rings, pullies, chest weights, etc. Care must be used in these exercises that the weakened set of muscles are exercised more than those on the well side; and the left-arm exercise for example is especially useful for the child who has a curvature to the right. Take the child and put it in different positions until you find what will best restore the curve, and then outline the exercises. By these, and the use of electricity and rubbing, the recumbent position and the carrying of weights on the head, the early cases can be cured; but when the disease becomes well confirmed and the vertebrae are really twisted out of place, we must try to force them back by the use of apparatus. This is difficult. Apparatus should not be used with the idea of being the only means, or the great means of cure; but only in bad cases, as a support, to prevent the parts from dropping over farther, until the muscles can be restored by proper gymnastic exercises.

The disease leads to terrible deformity if untreated. The child becomes dwarfed because the length of the vertebral column is lost in these curves. And some of the most marked deformities you see on the street are from this cause; at the same time there is nothing to interfere with the patient's living; and although remaining deformed, they may remain reasonably healthy; but after the vertebrae are thoroughly twisted, and the period of puberty is passed, and the growing age is beginning to diminish, a cure and perfect restoration to the upright form is almost impossible.

THE Royal Astronomical Society has awarded a gold medal to Prof. S. W. Burnham, of Chicago.

FIVE CASES OF CHOLECYSTOTOMY.

BY JOHN W. PERKINS, M.D.,

Senior Surgeon, St. Margaret's Hospital, Kansas City, Mo.

CASE I. Impacted gall-stone, with dropsy of the gall-bladder and abscess formation about the stone; recovery.

Mrs. B., age twenty-two, a well-developed, rather spare woman, I first saw in May, 1889, suffering from an intermitting fever apparently malarial in origin. There was no history or symptoms of gall-stones other than that she had been subject to "bilious attacks," and had been losing flesh for about eighteen months. Early in July she had an attack of diarrhoea with griping, apparently due to gross indiscretion in diet. This lasted a week, at the end of which, July 16th, she had a chill, vomiting, great pain, at first all over the abdomen, but later referred to the epigastrium and right iliac fossa. Pulse 140, temperature 102°. About twelve hours after the chill she noticed a tumor midway between the umbilicus and Poupart's ligament. This appeared as an ill-defined, rounded, fluctuating mass, slightly bulging the abdominal wall forward—tense, tender and dull on percussion. The area between it and the liver was tympanitic. Extension of the legs was painful. Five days later the acute symptoms had partially subsided; she was still vomiting, and in pain except when under the influence of opiates.

On July 21st I operated, Dr. E. W. Schaffler kindly assisting. Ether. The incision was made in the right linea semilunaris, from the level of the umbilicus, two and one-half inches downward. The peritoneum was much injected. The abdomen contained considerable thin, yellow, flaky fluid. The gall-bladder was one-quarter of an inch thick, free from adhesions, and contained over a pint of glairy fluid of the color and consistency of white of egg. There were three green gall-stones, the size of large filberts, in the sac, and a fourth firmly impacted in the cystic duct. The dislodgement of this stone was followed by a flow of about three ounces of pus into the sac. This had formed between the stone and the liver, evidently from ulceration of the stone through the duct. I sewed the gall-bladder into the wound, and she recovered with a fistula which closed six weeks after the operation. She gained flesh rapidly, and has remained perfectly well up to the time of writing, four years after the operation.

The points of interest in this case were:

(1) The youth of the patient, in connection with the fact that the gall-stones had been present for many months, if not years, as shown by their size, their many and well-worn facets, and by the great thickness of the wall of the much-distended gall-bladder. There had been no bile in the bladder for a considerable time, its walls being pearly white. The stone must have been impacted in the duct at a period antedating the dropsy of the bladder and the subsequent hypertrophy of its walls. I know of no data by which to estimate the time which such a process represents, but it is not improbable that the onset of dyspeptic symptoms beginning eighteen months previous to the operation marked the time of the impaction of the stone, and that the symptoms were the result of the continuous flow of bile into the intestine. The

chill in May, with the subsequent intermitting fever, was probably not malarial in origin, but was an instance of Charcot's hepatic intermitting fever, and marked the beginning of the inflammatory action around the impacted stone, which terminated in the ulceration of the stone through the wall of the duct, the abscess formation and the peritonitis.

(2) The degree of exactness with which this case presented Fitz's cardinal symptoms of appendicitis. A history of diarrhoea and griping for a week, at the end of which occurred a sharp attack of general abdominal pain, rapidly locating itself over the right iliac fossa, followed by fever and the appearance of a tumor within the necessary area, showed a rapid but proper evolution of the symptoms. The position of the tumor was higher and more internal than is seen in the majority of cases of appendicitis, yet not uncommon, for in twenty-four cases observed by me in which the situation of the tumor was noted there were two in which the tumor occupied this high superficial position. Mr. Treves¹ has called attention to the possibility of the cæcum and the appendix lying as high, even, as the liver, due either to the non-descent of the cæcum or an extreme mobility. He comments upon the possible difficulties of diagnosis in case of an attack of appendicitis in parts so placed. Similar difficulties arise from the encroachment of a distended gall-bladder upon the pelvic contents, as in the present case, and one, more marked, related by Mr. Tait,² in which the enlargement was so great that he mistook it for a parovarian cyst.

CASE II. Multiple gall-stones, with crystalline deposit in bile; hepatic colic for twenty years; recovery.

Ellen M., age forty, Irish, five children. Entered St. Margaret's Hospital July 24, 1891, after a severe attack of colic, during which her medical attendant, Dr. J. W. Thompson, thought several times that she was dying. She was a slight woman, thin-visaged, with a brownish-yellow skin, not jaundiced. She had had repeated attacks of colic for twenty years, the attacks lasting from one hour to a day, and frequently preceded by intense jaundice. For ten years past she has also had periodical attacks of so-called malarial fever two or three times a year, and had been confined to her bed for months on account of it. She was in a state of constant distress, even when free from the more acute attacks. Examination showed a marked degree of tenderness over the region of the gall-bladder, but otherwise nothing abnormal. Her urine on two examinations was alkaline.

On July 29th I operated, with the assistance of Drs. Gray and Bennett. Ether. The incision was made vertically, two and one-half inches downward from the end of the tenth rib. The gall-bladder was small, free from adhesions and very elastic, so that its fundus was easily brought into the wound. It contained bile and several rough, black stones varying in size from a pin-head to a pea. The bile was black, as thick as vaseline, so that it had to be scooped out with a spoon, and consisted for the most part of small, black, acicular crystals. There was upward of an ounce of this material. I sewed the fundus into the wound, and she recovered rapidly with a fistula which did not show any tendency to close. At night the flow of bile was great, drenching the dressings and running into the bed; during the day there was scarcely any. The stools were normal.

¹ Surgical Treatment of Typhlitis, page 11.

² Note on a Case of Cholecystotomy, *Lancet*, 1889, page 1294.

The failure of this fistula to close was due to the fact that I had sewed the mucous membrane to the skin, which was easily accomplished on account of the great elasticity of the bladder, whereas in other cases I united it to the cut edges of the peritoneum and transversalis fascia, and found that they closed spontaneously.

A year after the primary operation the fistula still remained open. On June 2, 1892, I made an attempt to close it by dissecting up the edges of the mucous membrane and sewing the freshened surfaces together. It held for three days, the viscus gradually becoming distended, until there was an immense gush of bile and the fistula was re-established. This was suggestive of an obstruction in the ducts, but the stools continued normal. Three weeks later I opened the original wound and dissected most of the gall-bladder away from the abdominal wall, leaving only a small portion adherent. After sewing the inverted mucous membrane, I united the peritoneum over it with a Lembert suture and sewed the abdominal wound tightly. It never reopened.

Since the removal of the contents of the gall-bladder, now two years, she has gained much in flesh, has lost her sallow color, and has had neither colic nor fever.

CASE III. Multiple gall-stones; contracted liver; resection of rib; recovery.

Frank S., age thirty-five, single, painter, American. Admitted to St. Margaret's Hospital August 25, 1891. He had been a soldier in the United States Army, but was mustered out on account of frequently recurring attacks of colic. Since 1883 he has had from two to six attacks every year; generally became jaundiced just before each attack; had found that large doses of Epsom salts tended to keep the attacks away, and always shortened them. He was a muscular, spare man, with high color, and had been a drinker.

The question of diagnosis in this case was important. He had had no attacks for six months previously, and had no physical evidence of gall-stones. He had been under the care of Dr. Walter, of Leavenworth, and his post physician, both of whom had made a diagnosis of gall-stones. The possibility of the colic being due to lead was directly suggested by the man's occupation. The fact that he had changed his occupation, and for six months had no attacks, gave it some color. The history of a well-marked jaundice preceding the attacks, and their comparatively short duration, seemed to help out the diagnosis.

Granting the hepatic origin of the attacks, were there any stones remaining in the sac? The patient insisted that there were. He dreaded another attack; and at his earnest solicitation I operated August 28, 1891. Ether. Drs. Schauffler and Porter were present.

A vertical incision was used, three inches long from the end of the tenth rib downward. He had a long, narrow chest, and his liver was tucked up under the ribs so far that it was impossible to get the gall-bladder down to the edge of the ribs. I was obliged to enlarge the wound upward and to resect the ninth rib, taking out about one and one-half inches to get the fundus into the wound. Moreover, the pitch of the lower surface of the liver was much greater than usual and the bladder placed well under it, so that it was necessary to push up the lower edge and partly rotate the liver in order to see it. On opening the gall-bladder, I removed eight irregularly angular stones of a bright-yellow color. With difficulty I sewed the fundus into the peritoneum and fascia, between the

ends of the resected rib. This wound suppurated around the stitches. I believe the great tension upon them was the cause. Bile flowed freely from the fistula and continued for about five weeks, when the fistula closed, and has never reopened. He has remained in excellent health up to the present time.

CASE IV. Multiple stones in the ducts (?); recovery.

Mary D., aged twenty-nine, American, four children. Entered St. Margaret's Hospital March 15, 1892. For two years past has had attacks of colic, lasting from two to seven days; is often jaundiced, and has taken a great deal of morphine, under the direction of her medical attendant, Dr. Drake. The attacks recur every two to four weeks, and are accompanied by fever. I saw her during one of the attacks. The symptoms were typical. Physical examination showed nothing beyond a very marked tenderness over the region of the gall-bladder. She was a large, stout, fleshy woman, with a white, pasty skin and a thick, rigid abdominal wall.

On March 19, 1892, I operated, with the assistance of Dr. Bennett. Ether. The same vertical incision was used as in the preceding cases. There were many tough adhesions about the neck of the gall-bladder, but the fundus was free. This I opened, and found one small stone. On passing the finger along the cystic duct, however, I felt a large stone in the adherent mass, and opened the duct from the outside after failing to dilate a stricture from the interior of the viscus. I removed the stone with forceps, and then found several more lying along the cystic and common ducts, the latter seeming much dilated. The stones extended beyond the reach of the finger so as to necessitate another incision in the abdominal wall at right angles to the first and parallel to the edge of the ribs. This admitted the whole of my hand inside the abdomen. I removed eleven large, brown, faceted stones from a dilated pouch, the largest was three-quarters of an inch in diameter. The line of stones extended beyond the middle line of the body, but in what they were contained — whether in the common duct, or whether they were encysted in a pocket into which they had escaped — I was unable to ascertain on account of the adhesions which had matted the parts together into an unrecognizable mass.

The slits in the duct were closed with catgut as well as the great depth of the wound permitted. I sewed a fold of the omentum along the adhesions below and the peritoneum above, to act as a shield in case an extravasation of bile took place. I also put in a drainage-tube with its lower end close to the slits in the duct. The fundus of the bladder I stitched to the edges of the abdominal wound.

The operation was difficult, long and tedious, and the patient suffered from some shock after it. She rallied, quickly, however, but vomited at intervals for a week. Bile flowed freely from the drainage-tube and from the wound on the day following the operation, but caused no trouble. The wound healed rapidly, leaving a fistula, which closed in about six weeks. Before this happened, however, she had an attack of colic similar to those which she had before the operation, but milder in character. After leaving the hospital, which she did on the first of May, she had several of these discouraging attacks. Just before an attack the wound would reopen under tension, and an immense amount of bile was discharged. There was much flatulence.

The attacks seemed to be occasioned either by taking indigestible food or making unusual exertion. Was there a stone left behind? I believed that the colic was occasioned in some way by the filling of the gall-bladder, and the stricture at its neck associated with the loss of the bile from the intestine. Pepsine and hydrochloric acid seemed to relieve her immensely, and the attacks soon ceased. She has had no attacks during the past eighteen months, has gained thirty-five pounds, and seems to be in perfect physical condition.

CASE V. Impacted gall-stone, with severe and prolonged vomiting; death from acute oedema of lungs due to ether (?).

Miss M., age forty-five, single, Irish. Was first seen in consultation with Dr. E. S. Ramsay, July 19, 1892. She had been sick three months. The attack began with pain over the right hypochondriac region, not especially suggestive of hepatic colic, and three weeks later a tumor could be felt over the region of the gall-bladder. There was no history of previous colic, jaundice or vomiting. A diagnosis of gall-stones had been made by Dr. Ramsay, and under the use of anodynes and hot applications the tumor slowly disappeared. The patient seemed to improve rapidly until the last of June, when she began to vomit, and developed a painful area in the epigastrium, just to the right of the middle line. The pain radiated along the left edge of the ribs and into the left shoulder — was paroxysmal in character, not increased by food. The vomiting and pain had steadily increased up to the time when I saw her, and she had lost much flesh and strength. She had been seen twice during the previous week by another consultant, who was said to have expressed the opinion that she had cancer of the stomach.

She was a large, fleshy woman, but very weak, and showed plainly the effects of twenty days of vomiting. Her respiration was short and rather quick, her pulse 90, and only fair in character. There was marked tenderness over the area of the gall-bladder and the epigastrium, but nothing like a tumor could now be felt anywhere in this region. She had no cachexia. Her urine and heart were both examined, but nothing abnormal was detected. Her lungs were not examined. An impacted gall-stone was diagnosed and operation advised.

On July 21st I operated, Dr. Ramsay assisting. Ether was given by Dr. Bennett, who has given ether for me in upwards of two hundred capital operations, and always skilfully. I wish to mention this especially on account of its connection with what follows.

The incision was made in the middle line of the epigastrium. The viscera were adherent to each other and to the abdominal wall by old firm adhesions which seemed most dense toward the region of the bile-ducts, and through which lay down a mass of gall-stones could be indistinctly felt. I could detect nothing abnormal, however, about the stomach, other than the adhesions at the pyloric end. I attempted to reach the gall-bladder through the adherent viscera, but it proved so difficult and large vessels were so numerous that I quickly abandoned the attempt and made a second incision directly over the fundus of the gall-bladder. The adhesions were here more recent, and the gall-bladder was reached with little difficulty. I removed five brown stones, the size of peas, from the bladder and four more impacted in the cystic duct, which dilated easily under the finger. This was fortunate, for it would have been impossible to have opened

the duct laterally, without the expenditure of much time. The work up to this point had been necessarily slow, partly on account of the very deep wound and partly on account of the proximity of the large vessels in the adherent mass, which rendered rapid work dangerous. No accident happened, however, and she had lost but little blood. During the operation, it had been noted that her pulse was rising, and after the first thirty minutes, was upward of 120, but strong and of good character. Digitalin (gr. $\frac{1}{100}$) and strychnine (gr. $\frac{1}{60}$) were administered at two separate times. The respiration had been excellent, except that on one or two occasions when tension had been made on the adhesions in the middle line, the breathing stopped for a moment but immediately began again on relaxing the tension. The mass of adhesions was evidently attached to the diaphragm. When ready to close up the abdominal wound, the patient had been under the anæsthetic one hour, four ounces of ether had been used in a Clover's inhaler, and the anæsthetic had been temporarily removed for several minutes, when her respiration suddenly became labored and pumping, her face cyanosed and her pulse indistinguishable. Bubbling râles could be plainly heard in the chest at every breath, and frothy mucus flowed from her mouth. She became quickly conscious in the struggle for breath. Fresh air and nitrate of amyl relieved her temporarily. Her pulse became much fuller and stronger, but she remained cyanosed and the frothy mucus still bubbled from her mouth, the respiration still being shallow and pumping. The operation was rapidly completed without further anæsthetic, and the patient put to bed. For two hours she remained cyanosed, her respiration short and jerky, her chest bubbling, her pulse rapid and rather tense. She then sank rapidly, and died cyanosed two and one-half hours after the operation. Neither the cold, clammy, pallid skin of shock nor the pale restlessness of an internal hæmorrhage were present.

I afterwards learned that she had had at least two similar attacks of so-called "capillary bronchitis with hypostatic congestion and oedema" of the lungs, which had barely disappeared two weeks before the operation, the time when her lungs were last examined. No worse subject for ether could have been found.

REVIEW OF A SUMMER'S WORK IN GYNÆCOLOGY AT THE BOSTON CITY HOSPITAL.¹

BY JOHN G. BLAKE, M.D.

IN reviewing the summer's work in Ward S, a few words outside of the regular tabulated results may not be out of place. These remarks may be considered in the light of conclusions by the writer upon subjects treated up to date. While they contain nothing absolutely new, they at least enable him to revise previous opinions. And first a few words concerning

ALEXANDER'S OPERATION.

This has been performed by the reader eighteen times during the summer, usually at the City Hospital. The results, in all but two cases, were successful. In one, the ligaments appeared to be in a state of fatty degeneration. That on the left side broke off so easily that it was not deemed expedient to undertake shortening the one on the right. In the other, there was so

¹ Read before the Obstetrical Society of Boston, October 14, 1893.

much gluing together of the parts from old peritonitis, that it was impossible to draw the ligaments out on either side. A third case, at St. Elizabeth's, had a ligament on the left side no larger than a knitting-needle, while that on the right was rather above normal size. There was no difficulty in finding them, and the union was perfect in every case. Not a drop of pus formed in connection with any of these operations, which shows that antisepsis was carefully attended to. All proved perfect surgical successes; and therapeutically they were equally so, relieving completely the pain and pressure which called for their performance.

The question of permanence of relief, is often raised by those who have not done the operation, or who for any other reason are opposed to it. Pregnancy is quoted as entirely destroying the benefit acquired. In three cases, to my personal knowledge, and by careful examination, the position of the uterus remained unaffected by childbirth. Two were my own operations, and a third, operated upon in Lowell, had the same result. Dr. Davenport, in the *Boston Medical and Surgical Journal*, Drs. Johnson, Kingman, Conant, Burrage, and others whom we all know, say the same. If it were necessary, the writer could obtain a mass of absolutely incontrovertible testimony on this point. So it may be considered settled, that Alexander's operation neither prevents pregnancy, nor is impaired by that condition. On the other hand, the permanent emancipation of woman from dependence upon pessarials, is to my mind ample justification for the operation in cases of chronic displacement. Its simplicity, comparative freedom from serious results, and short period of confinement to bed, are large elements in its favor.

DILATING AND CURETTING.

This comparatively new substitute for the old, tedious and unsatisfactory treatment, by laminaria tents and repeated applications of iodine and acids, has been done sixty times without any unpleasant result to the patient. It has been resorted to in chronic endometritis, with or without catarrhal discharge; in prolonged metrorrhagia — narrowing or bending of the uterine canal, causing sterility or severe dysmenorrhoea; catarrhal salpingitis, where prolonged drainage was required; and ovarian pain independent of organic change. In cases of subinvolution it was also tried; and whenever it became necessary to explore the endometrium, it was found to be the quickest and safest means. Other conditions of the uterus, like hyperplasia, and granulations, are familiar to all, and need not be enumerated. I am prepared to speak very favorably of the results in many of the above conditions, while but moderate success attended others. For instance, in a case of chronic endometritis with endocervical discharge, a single operation will often diminish the size of the organ and absolutely stop the discharge, leaving a healthy normal uterus, and a cervix almost virginal in appearance, shape and size. I have seen this result so often that it is easy to foretell it. On the other hand, in the relaxed, flabby, or leaky uterus, the best results after dilating, followed the application of a mixture of Churchill's iodine and carbolic acid, or Monsell's styptic, to the endometrium, instead of packing with iodoform gauze. It must be borne in mind, that the condition is often only a symptom of a state of constitutional debility, and that local should be associated with general treatment. Acting upon this hint will often

save disappointment. The same remark will apply to all cases of pelvic inflammation of long standing, which are usually associated with marked debility and anemia — the result of pain and confinement to bed. Finally, it may be necessary to repeat the operation after an interval of two weeks or more.

In several cases I have seen marked benefit follow a repetition of the dilating, without or with the gauze packing, where a severe form of chronic enlargement of the uterus existed; or persistent salpingitis, in which long-continued drainage might be of advantage. The operation may be considered in the light of a very safe time-saver, since it enables one to accomplish in a few weeks what in old times would have taken months.

In cases of sepsis following labor or miscarriage which were treated in Ward S, and of which we had fourteen during the summer, the results were not always successful. Two terminated fatally from lung complications and septic pneumonia. This was after the utmost care in treatment of the endometrium combined with active general treatment, including the use of salines. In both, the tubercular diathesis was well marked. From observation extending over many years of general practice, I have reached the conclusion that there is marked susceptibility to this form of sepsis, where the diathesis exists. I should not, because of this, modify to any degree the thoroughness of treatment, but would not feel the same confidence in its result. On the whole, the success attending the method has been gratifying, and justifies the remark of Dr. Richardson, that "if we cannot always prevent the disease, we may often cure it."

The cases of pelvic abscess were eight in number and yielded to incision and drainage through the vagina. One, transferred from the medical department, where it had been admitted by mistake, was an exception. Here the abscess had burst into the rectum, establishing a fistulous opening. This closed after a time of careful, constant drainage, but the original abscess cavity showed little tendency to contract. The subject was a wretchedly poor one for treatment; a confirmed inebriate, anæmic and flabby, without strength to set up reparative action. At the expiration of my term of service, my advice was that she be transferred to the surgical side for removal of diseased pelvic tissue by laparotomy, as soon as her condition justified. Dr. Burrill removed the left tube and ovary; but the patient died three days after. Another case, treated at St. Elizabeth's by suprapubic incision, contained nearly a pint of fetid pus, got well rapidly. Two cases of chronic inflammation of tubes and ovaries, were transferred to the surgical service and the diseased tissues removed successfully. These were the only ones, which in my opinion justified resort to laparotomy. The number is certainly small in view of the frequency of the operation in these days, and the number and character of cases treated.

We become more conservative as we advance in years, and are loth to give up old and tried methods for those more dangerous and brilliant. Hence we prolong our efforts on the old lines, with a success that is gratifying. Even the younger and more enthusiastic laparotomists are beginning to pause and consider, whether milder means, longer continued, may not after all be the best treatment in many forms of chronic pelvic inflammations. I dislike to be classed as a foggy, but will not the experience of the older men of this Society bear me out, when I say, that many of the

conditions for which laparotomy has been done of late years would have yielded to patient, persevering, non-operative treatment? Dr. William Goodell, in the *Medical News* of December 9th, takes the same conservative view.

In the matter of malignant disease of the pelvis, the number was twelve. None of the cases were suitable for radical operations, with one exception. When the body as well as the cervix was involved, and it was reasonably sure that the disease had affected the pelvic glands and uterine appendages, the diseased tissue within reach was removed by curettes, scissors, actual cautery, and acids. By careful after-treatment, the disease can be kept in subjection, and immunity from pain and hæmorrhage assured. Life may be made endurable for a considerable time — from one to three years. On the whole, I cannot see that this is not as satisfactory as the results following more radical measures. When Dr. Chadwick says that all his vaginal hysterectomies died within a year, and Matthew Mann states that none were living at the end of five years, it seems scarcely worth while to go through so much for such doubtful gain. I am quite convinced that the day is not far distant, when surgeons in the light of their experience with malignant breasts, will be satisfied to leave the treatment of advanced malignant disease of the uterus, to palliative measures alone.

One case had the disease at the fundus, with no indications at the cervix; uterus enlarged, with only slight local symptoms calling for treatment; but rapidly running down, and with marked cachexia. The patient was not treated locally farther than to explore and ascertain the nature and extent of the disease. She was put upon supporting and alleviating treatment, sent home, and is still living.

A very rare form of epithelial disease of the vulva, invading to some extent the vaginal walls, was sent in by Dr. Edward Reynolds. There seemed to be no infection of the pelvic glands. The disease was thoroughly removed and but little deformity of the parts resulted. Time alone will determine whether the disease returns.

As will be seen, I have commented briefly on some of the operative cases; and while there is nothing very new in the report of such a service, there is confirmation of the success of old methods, which, to the older members at least, may afford satisfaction.

The following are the tabulated results prepared by Dr. S. E. Courtney, my very efficient senior house-officer, with the records of two cases which seemed of special interest to him:

CASE I. A. R., single, twenty-three years of age. Dysmenorrhœa since the establishment of menstruation. Examination showed the cervix to be acutely anteflexed, with stenosis of internal os and some endocervicitis. Extremely nervous. The uterine canal was dilated, curetted and packed with iodoform gauze. The gauze was removed from the uterus on the sixth day, and the patient discharged on the tenth day. Four months after operation the patient reports that she has no dysmenorrhœa, and has almost entirely recovered from the previously existing nervous symptoms.

CASE II. A young married woman; always suffered from dysmenorrhœa. She became subject to epileptic seizures immediately after her marriage. These attacks often numbered twelve a day, and had continued for six months. In order to straighten and enlarge the uterine canal, it was thoroughly dilated and packed with iodoform gauze. After the usual period had elapsed, the gauze was

removed. Subsequent examination some weeks after, with a view to inserting a stem-pessary, showed that the uterine canal freely admitted a large-size sound, and did not seem to present more than the ordinary curve of a virginal uterus. Patient has not had an epileptic seizure since the operation, and has steadily improved in health and strength. She has menstruated once since the operation was performed, with but slight pain. In view of the fact that the epileptic seizures apparently resulted from an aggravation of the dysmenorrhœa resulting from marriage, it is only reasonable to hope that the result will be permanent.

BOSTON CITY HOSPITAL.

GYNÆCOLOGICAL OPERATIONS BY DR. JOHN G. BLAKE, DURING HIS FIVE MONTHS' SERVICE.

<i>Dilatation and Curetting</i> , 60 cases.	
Endometritis, endocervicitis, salpingitis, etc.	43
Stenosis — Sterility	12
Anteflexion of cervix	5
Two cases of salpingitis transferred to Surgical Department for laparotomy; tubes and ovaries removed; discharged well.	
<i>Operation on Lacerated Cervix</i> , 19 cases.	
<i>Operation on Lacerated Perineum</i> , 18 cases.	
One operation had to be repeated.	
Cervix and perineum on same patient	8
<i>Alexander's Operation</i> , 18 cases.	
Right ligament not found in two cases.	
Ligaments small and adhering in the ring in one case, failure.	
Ligaments undergoing fatty degeneration in one case, failure.	
The most satisfactory result was an Alexander and perineum operation for complete prolapse of the uterus.	
Sixteen discharged well.	
<i>Septicæmia</i> , 14 cases.	
Six died and eight were discharged well.	
<i>Cancer</i> , 12 cases.	
Two died, nine relieved, and one, sarcoma of vulva, discharged well.	
<i>Pelvic Abscess</i> , aspirated and drained by tube per vagina, 8 cases.	
Three discharged well and five relieved.	
<i>Vulvo-Vaginal Abscess</i> , 7 cases.	
All discharged well.	
<i>Cystocele</i> , 5 cases.	
All failures in as much as stitches gave way.	
<i>Fibroids</i> , 5 cases.	
Removed in two cases only.	
<i>Pelvic Hematocœles</i> , 3 cases.	
One died and two relieved.	
<i>Uremia of Pregnancy</i> , 3 cases.	
All died.	

Clinical Department.

A PERSONAL EXPERIENCE WITH SMALL-POX.

BY H. WARREN WHITE, M.D.

THIRTEEN years ago, amidst the pleasantest memories of my life, there happened an event which in comparison was like a horrible nightmare.

After graduation in June, 1880, I had the good fortune to spend a year abroad. I had enjoyed immensely the sights and sounds of Berlin, Dresden and Vienna. I had been up the Rhine and down the Danube, as I had never expected to do. My dreams of European travel had become happy realities; and at last I had spent some months in Paris, the most enjoyable experience of them all.

Here I had applied myself to medical studies more thoroughly than elsewhere. I had taken courses and clinics with Jaccoud, Charcot, Fournier, Parrot and Latteux. The remembrance of those days is delightful. I enjoyed and profited much during that winter of 1880-81. But amidst that success and happiness I was to have a Waterloo indeed!

During the last week in February, while making a hospital visit in a children's hospital with Professor Parrot, I remember for the first time in my experience seeing three or four cases of variola that for some reason had been isolated and cared for in a distant wing of the hospital. It was nearly noon at the end

of a long visit. I had only a roll and a bowl of chocolate for breakfast those mornings, and was already feeling the need of my breakfast with a fork, as they call it. Before entering these apartments Parrot turned to the fifteen or twenty students and asked us if we were vaccinated, for if we were not, he would not advise us to continue the visit. Three or four turned back, but I went in with the others; for it occurred to me I had no need to fear this contagion. I had been successfully vaccinated when a baby and again when about fifteen years old; and an attempt at revaccination when in the last year in the medical school had been unsuccessful. I considered myself to have immunity from the disease, although this last time referred to I was vaccinated by a fellow-student with virus which I have since suspected was inert.

The cases under Parrot's care were all children; his prognosis very grave. Their appearance was *sickening*; and the stench-laden atmosphere I had good reason to remember again in about two weeks. This peculiar odor, once thoroughly appreciated, I believe can never be forgotten. It is like nothing else.

This exposure to variola was a positive one, occurring but once and lasting not over fifteen minutes. I handled neither patient nor anything in the room, but simply inhaled this heavily-charged atmosphere while tired and in a hungry condition. This was the first part of the last week in February. My medical course ended with the month of February; and so promptly on March 1st, I left Paris at 7 A. M., and ate dinner at the Bedford Hotel, London, at 6.30 P. M. of the same day. I felt particularly well; and while crossing the English Channel I was not in the least seasick, although the passage that day was more than ordinarily rough.

I came to London on Tuesday, settled quickly in my new quarters, arranged to attend a surgical clinic of Lister's; and Friday made my first visit with him at King's College Hospital. On Saturday I felt unusually tired and weak, and Saturday night was in alternate fever, sweats and chills. It was about ten days now since my exposure, which occasion had wholly passed from my mind. Sunday the 6th, was quite sick; a miserable feeling throat; sore and lame all over; something like an approaching tonsillitis, to which I had ever been very liable. Hoping to improve by going out, I rode to Bloomsbury Chapel. Did not enjoy my trip out; nor the sermon, although pronounced by good judges to be a most excellent one. My headache increased, with dizzy, giddy sensations. Glad to get back to the hotel and stay in the rest of the day. In the afternoon I noticed an erythema on the back of my hands and wrists, which increased. Complete anorexia. Temperature $101\frac{1}{2}^{\circ}$. In bed I felt better; and although my sleep was disturbed and uneasy, I worried through the night without calling for help.

Monday morning I was much worse; could not possibly suffer more backache and headache; tried to sit up; vomited. Temperature 104° . Erythema on hands and face, chest and abdomen now very marked. Called the landlord; and he, frightened at my condition, called his physician, Dr. Hall. In a careful, deliberate fashion he diagnosed scarlet fever as the trouble we had to deal with. He called my attention to the fact that a hotel was no place to be sick in (I should have known better, of course). Said I must go at once to the London Fever Hospital; that it would take all day to get an ambulance, and that the

law forbade using a public cab. It was "only a mile away," and I must walk! Somehow—I never remembered just how—I hastily packed and locked my luggage, carelessly dressed, and walked (with Dr. Hall's help) through the streets to the hospital. He dropped me at the door, and I dropped after I got inside. Was given a private room and special nurse, in honor of my youth and profession. Temperature after entrance 105° . Dr. Smith, of the staff, diagnosed scarlet fever. The fact that I had never had it and that it was very prevalent just then in London made it seem quite likely. Although variola later became very common in the city, just yet it had not become epidemic.

Tuesday. Still sore-throat, headache and high fever. The rash did not act typically, and some doubts were expressed as to its being scarlet fever. It had faded instead of increasing. Some one suggested variola. That day I remember how aggravating and unnecessary the noises of a hospital seemed to me. People talked incessantly; dishes rattled; doors slammed; ward trucks squeaked excruciatingly, and the wheels rattled miserably. I vowed, if I got well, I'd buy some lubricating oil and rubber tires, and present them to this hospital. I would tell them how much a poor devil suffered from noises which could be prevented.

Wednesday morning, before light, I detected about myself that odor which was unmistakable. I recognized the flavor of two weeks ago. I could not wait for daylight. I called the nurse, and told her I had no doubt now what I had, and to inform the house-officer at once that I had small-pox. She hastened away without a word. I put my hand to my face, and felt what seemed like a lot of bird-shot just under the skin of the forehead along the edge of my hair. The house-officer came at once, and confirmed my diagnosis. You can scarcely guess what chagrin, confusion and distress I caused in that hospital; and to make matters worse they had to wait all day long till evening for the small-pox ambulance to come for me. They would have got rid of me before, but they did not dare to use their own ambulance. I remember that ride very well. Their small-pox ambulance was constructed something like an American hearse. The patient was wrapped in blankets, shoved in, and the doors shut. It was like attending your own funeral. Lying in there and easily looking out the glass sides at the happy, healthy people walking the sidewalks, made me feel extremely miserable and unfortunate.

Thus I entered Highgate Small-Pox Hospital on the evening of Wednesday, March 9th, an unwelcome encumbrance. The first night there, I believe, was the most terrible in my whole experience. I arrived late, and was put into the centre of a long ward with twenty or thirty others. A howling snow-storm outside. There were large ventilators over each bed (like those in dissecting-rooms), and they were so wide open I felt the snow sift in upon my face during the night. The patient in the bed to my right was in a howling delirium all night long, but quieted down and died about daylight. Another died across the room, three beds away, on my left. There were no screens to put around them. There were only a few private rooms, and those were occupied by women. They changed my bed to the end of the room next day, where, by turning to the wall, I could avoid seeing the misery around me. There was no attention worth calling nursing, as good nurses would not accept such a position. The nourishment dealt around was thick

slabs of bread and butter and a bowl of tea. My mouth and throat were very sore, and I could not eat anything like this. After much begging I got some milk. For three days after that I had a wild delirium, more, I expect, from the excitement and shock of my experience than from the intensity of the disease, though the attending doctor said I was very sick and was part of the time in a camisole. My face was swollen and painful, and my fever ran high. I would not stay in bed. Was continually trying to extinguish imaginary fires, rescuing myself and bedding from the blaze. Once they found me with a handkerchief tied tightly around my neck, and I asked for a short stick to thrust under it and twist it to strangle myself. All such fine plans were prevented, and full doses of chloral and bromide taken after much persuasion. Some dim recollection of all this I have still—the most horrible remembrance of my life.

I saw myself for the first time on the following Monday (clothed in my right mind). Nobody would recognize me. It appeared as if my face had been burnt with steam or powder. I would not know myself. I feebly asked the doctor if this was a case of varioloid. I remember how he laughed. I tried to laugh, but it hurt me too much. I looked at my chart, which he showed me—"Discrete variola vera." This I felt had been the true article sure enough. There was a fee of four guineas, I found out, due the hospital for all this elegant entertainment; and I got the landlord to advance the same on the strength of my luggage still in his possession.

Tuesday, Dr. Smith, of the London Fever Hospital, sent me some oranges, grapes and flowers; but my mouth was too sore to eat the fruit, and somebody stole my flowers.

I went into the convalescent ward on March 16th. My face, itching unbearably, was relieved on application of carbolized vaseline. My companions here were very dull and stupid. The weather outside was stormy most of the time, the epidemic increased, and the hospital was crowded to the doors. Diet: boiled mutton and ale, t. i. d. Later I used to make the rounds with Dr. Goude (as my strength improved). I remember one remarkable case of hæmorrhagic small-pox in an old man. This man entered strongly pitted. It was his third attack. His skin was purplish. He was bleeding from every orifice of his body—mouth, nose, ears, bladder, rectum and stomach—and very conscious of his serious condition. He never broke out fairly before he bled to death. Deaths occurred daily. The mortality of confluent cases was nearly fifty per cent.; of the discrete cases, six per cent. It was very dull and lonesome to me; and it was too sickening for me to have much interest in it all, though the doctor did all he could for me. The horror and distress of a severe confluent case must be seen to be appreciated,—the phlegmonous face, swollen beyond possibility of recognition, swollen so that the eyes cannot be opened; the tongue protruding, so much swollen it cannot be held in the mouth; the foetid breath, drawn with great difficulty and much noise. Happily such patients are comatose, muttering or groaning in a typhoid-like condition, finally getting exhausted and giving up the struggle, or wonderfully living on, day after day, without nourishment, and finally recovering (in some cases most miraculously), but carrying the scars of the terrible struggle as long as they live. I was particularly sorry to lose the

night nurse, who had been very kind to me. She was found to drink the brandy ordered for the patients. I knew before that she had been drinking by the odor; but I was not surprised, considering what a place that was to work in. There was often in the night a confusion of howls from the long ward. Poor lunatics! I could scarcely believe that a few days before I was as delirious and making as much confusion as any of them. Many hundred patients passed through that course and graduated into the convalescent wards while the epidemic raged; but many others went the way to the dead-house.

On March 22d I took dinner once more like a civilized being, this being down-stairs with Dr. Goude, in his private apartments. I told him how poorly his patients were being nursed. He seemed to be much surprised and shocked to hear of it. I never knew if it was changed, or if it could have been; and in writing this I fully realize how much easier it is to point out defects than to remedy them.

On March 23d, after a thorough carbohc bath and baking of my clothes (letters sent out were thus baked), I was given my liberty once more. Although too weak to walk then, in about a week I was thoroughly convalescent. Always anæmic, I was extremely so for a month afterwards; my breath short and pulse rapid on the least exertion. I lost ten pounds. The only special treatment I received was sedatives for nervous symptoms; cold, wet cloths to the face, and carbohc ointments later; ice for the throat; and stimulants freely during convalescence.

I went later to the London Fever Hospital, and gave them £1. 1s. for their trouble (I hope they oiled the truck-wheels), and paid £3. 8s. 6d. to the landlord to cleanse my rooms at the Bedford and fumigate them properly, a nice little sum of between eight and nine guineas in all for my rather unusual *clinical* experience.

I could not help learning a few things about variola during this vivid experience which may be interesting just now:

- (1) The feeble protection of old vaccinations.
- (2) Importance of successful re-vaccination.
- (3) That a previous attack or vaccination give about equal protection.
- (4) "Varioloid" is not only a foolish, but a dangerous superstition.
- (5) The intense virulence of variola.
- (6) The long incubation.
- (7) Difficulty of diagnosis.
- (8) Rapidity of the disease and its stages.
- (9) The very general eruption on inner mucous and serous membranes, alimentary tract from mouth to anus, trachea, bronchi, urethra, vagina, conjunctiva.
- (10) Horror of the disease because of the isolation necessary, the pain and odor and delirium, and the poor nursing generally.

REPORT OF TWO PREGNANCIES FOLLOWING A LAPAROTOMY.¹

BY N. F. CHANDLER, M.D., MEDFORD, MASS.

OCTOBER 11, 1892, I was called to see Mrs. G., who gave me the following history: Age thirty-six. Family history not remarkable. Up to the time of

¹ Read by invitation before the Obstetrical Society of Boston, October 14, 1893.

her marriage, in 1880, she considered herself well, though not specially strong. About a year later, or in 1881, she began to have trouble which led her to consult Dr. C. M. Green. She was under his care until the fall of 1883, when she went to Dr. John Homans, who performed laparotomy November 21st, removing a cyst of the broad ligament. For four years after the operation her general condition was not good. She could not ride or walk any distance; even slight exertion caused fatigue. The catamenia were irregular, seldom more than three weeks apart, profuse but without much pain. In 1887 she began to improve in health; and in the latter part of that year she became pregnant. Before a diagnosis of pregnancy could be made a mucous polypus was removed from the cervix by Dr. C. M. Green, April 27, 1888. During this pregnancy, which was ended by miscarriage between the fourth and fifth months, her condition was apparently normal. She had the usual morning sickness, but nothing more. She had little or no unusual discomfort, and her general health steadily improved. So far as I have been able to learn, the cause of the miscarriage could not be explained, though the patient thought she had done more walking than usual, and felt that that may have been the cause. After the miscarriage her health was better than before; but even then she was not very strong, though she suffered from no particular ailment. If she became overtired or run down she was likely to have stomach trouble — food causing some distress and occasional vomiting. During June and July, 1892, she was not as well as usual.

From August 1st to the 8th, she was unwell as usual; and this proved to be the last regular period before a very trying pregnancy, though on August 28th she began to have some irregular flowing, which continued at intervals until September 14th, when an examination made by Dr. C. M. Green led to the discovery and removal of a cervical mucous polypus, after which the flowing soon ceased.

Three weeks after her last regular period she began to be troubled with nausea and vomiting, which soon became so bad as to interfere with her taking and retaining proper nourishment. She found she was losing flesh and strength and on October 10th I was called to see her. At this time she was fairly well nourished, though rather anæmic. Physical examination showed nothing remarkable. Temperature was normal and remained so all the time. Urine examined at that time, and frequently during the pregnancy, was always found to be normal. Bowels were constipated. Uterus could not be felt above the symphysis. At this time nausea was constant, and she was able to retain very little nourishment. After October 12th she was kept in bed, trying different articles of diet and various medicines to overcome the vomiting. We met with little success, however, and she continued to lose flesh and strength, though not as rapidly as one would have expected considering the small amount of nourishment she was able to retain.

On November 20th she was seen by Dr. Green, and a diagnosis of pregnancy was made. A few days later all vomiting ceased, and she was able to retain food without discomfort. Thinking the miscarriage five years previous may have been due to adhesions, resulting from the laparotomy, preventing the uterus from rising as it naturally would, the patient was kept in bed until January 1, 1893, or until the end of the fifth month. After this she was up and about her

room, but did not go down stairs until March 15th. At this time she was in a very good condition, having gained rapidly as soon as she was able to retain her food. She continued to take excellent care of herself, avoiding any exertion, going over the stairs only once a day and occasionally walking out on the veranda.

On the morning of April 2d I was called in haste to see her. I found her suffering from frequent severe abdominal pains, and with each pain the uterus could be felt to contract. Vaginal examination showed the uterus to be high in the pelvis, the cervix not taken up and the os not dilated. Fœtal heart distinctly heard on the left side. Sufficient morphine was given to check the pain at that time; but during the next two days the pains would return as soon as the effect of the morphine would wear off, and more had to be taken. April 5th she was free from pain, but nausea and vomiting were more troublesome than ever. She was not able to retain any food, and suffered constantly from nausea, whether taking food or not.

This condition of things persisting, in spite of efforts made to check it, Dr. Green was asked to see the case again April 10th. He found the uterus low in the pelvis, the head presenting, os admitting finger-tip. He believed we had better delay any operative interference for the present, in the meantime trying rectal feeding, and keeping close watch of the case.

On April 25th, or at the end of the eighth month, the mother's condition was such that further delay was thought inadvisable in the interest of both mother and child. Ether was given, and Dr. Green did manual dilatation, turning the child and delivering without any great difficulty and in a short space of time. After the mother had recovered from the ether there was no more vomiting, and her convalescence was uninterrupted. The child, a girl, appeared to be in very good condition when born, and did very well for twenty-four or thirty-six hours, when it began to have convulsions; and it died on the third day.

The points of special interest in this case, as they occur to me, are, the history of two pregnancies after an operation which changed the condition of the ligaments which hold the uterus in place, and probably left it less free to rise above the brim of the pelvis; the coincidence of a cervical mucous polypus appearing early in each pregnancy; and the obstinate vomiting which came on as soon as there was any unusual pressure in the cavity of the pelvis, and remained until that pressure was removed.

Medical Progress.

REPORT ON DISEASES OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, A.M., M.D.

(Concluded from No. 3, page 65.)

CEREBRAL INFANTILE DIPLEGIA.

FREUD¹⁰ unites under the above heading four types of cerebral disease: (1) General rigidity of cerebral origin (Little's disease); (2) Paraplegic rigidity (spasmodic tabes dorsalis of children); (3) Double spastic hemiplegia; (4) Congenital general chorea and double athetosis. General rigidity of cerebral origin has two fundamental characters: the lower extremities are much more affected than the upper, and

¹⁰ *Revue neurologique*, 30 April, 1893.

the phenomena of contracture exceed those of paralysis. It is also distinguished by a slowing and diminution of the cerebral influx on the co-ordinated actions of standing, walking and articulate speech, and by a varying degree of mental impairment. Strabismus is common; atrophy is absent; convulsions are frequent soon after birth, but they do not continue. The affection remains stationary with a tendency to improvement. Many writers consider double hemiplegia as closely allied to this, but others make a sharp distinction. Paraplegic rigidity, once thought to be purely of spinal origin, is shown, by the occurrence of strabismus and mental impairment, to be allied to general rigidity, but to be of a less severe type. Both of them are regarded by Freud as related and connected by many transition forms. The general form may improve until there is only a trace of rigidity in the arms, when the case resembles the paraplegic form. In other respects they are very much alike. In the general form there may be more or less paralysis, or a facial paresis, which forms a link with the cases of double spastic hemiplegia where paralysis predominates, and these transition cases are much more often seen. Cases of diplegia may also show transitions toward paraplegic rigidity. To produce double hemiplegic intra-cerebral or deep bilateral lesions are necessary, but superficial lesions, especially near the median fissure suffice for general or paraplegic rigidity; and the meningeal hæmorrhages of difficult labor afford precisely the lesions required. Congenital chorea and double athetosis may be classed with the cerebral diplegias, for in ordinary spastic hemiplegia it is not unusual to see similar motor troubles develop after paralysis, post-hemiplegic chorea. In other cases the chorea is manifest from the first, choreic hemiparesis. If this be the case in hemiplegia it must also be the case in double hemiplegia. Chorea and athetosis are also found in cases of rigidity. Consequently Freud would class them all under the one head of cerebral diplegia. Difficult labor is an important etiological factor in all four forms, premature birth only in the cases of general or paraplegic rigidity. Rigidity may also follow acute infectious diseases. Freud rejects classifications of the causes, and thinks it by no means easy to say, in cases where the symptoms do not manifest themselves until a year or two after birth, that the trouble was not of congenital origin. Many children are born before term or after difficult labor, but they have not diplegia, hence there must be a predisposing factor beside the accidental factor of traumatism. In syphilitic cases this factor may be regarded as the fragility of the blood-vessels, hence it is not illogical to suppose a similar state of the vessels in debilitated or cachectic children. It is a curious and unexplained fact that epilepsy is common in double hemiplegia and spastic hemiplegia, but extremely rare in general rigidity and athetosis.

EPILEPSY.

Hohn¹¹ regards as epileptic cases of sudden and periodic losses of consciousness, to which are generally joined convulsions of a definite type, without any notable modification of the central nervous system visible to the naked eye. In three cases which he has studied microscopically, he found an increase of the cells of the neuroglia, a thickening of their ramifications, an absorption of the intercellular substance, a considerable growth of new vessels and a weakening of the nervous

net-work. As a rule these changes are seen chiefly on the lateral face of the convolutions. In one case he noted a colloid degeneration of the ganglion cells, evidently connected with death during an attack. The insula and the gyri recti and fornicati were most affected. In the internal capsule was seen a degeneration of the fibres coming from the hemispheres, especially the motor fibres. In the pons, medulla and cord the pyramidal fibres were partly degenerated. Epileptic attacks may be explained by an irritation of the cortex alone, but a generalization of the attack demands that the bulbar and spinal fibres be equally involved. Hohn believes that the attack itself is due to a vaso-motor process, in the course of which venous stasis with acute oedema is produced in the central nervous system.

Fournier¹² recognizes as occurring in syphilis a form of epilepsy very different from what is ordinarily termed syphilitic epilepsy, or rather the epileptic form of cerebral syphilis. This form of epilepsy appears as an isolated symptom, without any other general or cerebral phenomena, and it continues under this form without association with other marked phenomena. It lasts a long time, it is neither cured nor checked by antisyphilitic remedies, but it is relieved, although not cured, by the bromides. True syphilitic epilepsy, on the contrary, is associated with other cerebral phenomena, rapidly assumes the symptoms of a specific encephalopathy, progresses more or less rapidly toward a cure or toward a fatal termination, and is very often benefited by antisyphilitic remedies. He cites a case in which, twenty years after infection, at the age of forty-five, epilepsy developed and continued without other complication for eleven years. Antisyphilitic treatment was useless, but bromides checked the frequency of the attacks, and was the only thing that did any good. In this form of epilepsy the invasion is sudden, unexpected and spontaneous; it comes on in full health, without prodromes or apparent cause. It usually begins with an attack of *grand mal*, but later *grand* and *petit mal* may be associated. The attacks of *grand mal* are like those of ordinary epilepsy, but they are not very frequent, the attacks of *petit mal* are much more frequent and may increase in frequency, even replacing the attacks of *grand mal*. This form of epilepsy occurs in the tertiary stages of syphilis. Fournier thinks it due to syphilis on account of the clear previous history, the advanced age at which the convulsions begin, by the absence of any other cause, and by the occasional co-existence of true syphilitic accidents. It differs from syphilitic epilepsy in that it is never partial, never is associated with other cerebral symptoms, lasts for years and never yields to antisyphilitic treatment. It is derived from syphilis, but, like tabes, it has not the nature or the essence of a syphilitic manifestation. Hence Fournier would call it "parasymphilitic epilepsy." Mendel's investigations, showing that epilepsy is not very infrequent after thirty in non-syphilitic subjects, make it doubtful whether Fournier's cases are really to be regarded as a special type.

Epilepsia tarda. — It is a well-recognized fact that the great majority of cases of epilepsy begin before the age of twenty, and a number of years ago Delany classed cases beginning after the age of thirty as "*epilepsia tarda*." Mendel,¹³ after a careful exclusion of

¹¹ Nordisk. medic. Arkiv, No. 15, 1893.

¹² Revue neurologique, 30 November, 1893.

¹³ Deutsche medicinische Wochenschrift, 9 November, 1893.

all cases simulating epilepsy, has studied 904 cases coming under his own observation. Contrary to the statements of Reynolds and Nothnagel, he found the male sex more disposed to the disease, 555 of his cases occurring in men. The largest number of cases begin between the ages of ten and fifteen, and over two-thirds, 628, before the age of twenty. From the age of twenty the frequency of epilepsy becomes distinctly less, but in the decade from thirty to forty no less than 99 cases began, so that Mendel justly takes exception to regarding the onset of epilepsy during that period as particularly remarkable, and only for the cases which begin after the age of forty would he admit the term "*epilepsia tarda*." After the age of forty epilepsy becomes much less frequent, only 53 cases beginning after that age, and only three cases (one man and two women) occurring after the age of sixty, the man being sixty-one, and the women sixty-two and sixty-three. Mendel's figures agree with the statements of Bennett and Gowers that *epilepsia tarda* is commoner in men, 38 cases occurring after the age of forty in men, and 15 in women; 6.8 per cent. of all cases of epilepsy in men may be classed as *epilepsia tarda*, and 4.8 per cent. of all cases in women. Delany found hereditary taint in one-half of the cases occurring after the age of thirty. Mendel accepts this view, for in one-fourth of his cases, where the history of any hereditary taint was hard to be obtained, owing to the social condition and the advanced age of the patients, he found clear evidence of such a taint. The direct exciting causes of *epilepsia tarda* seem to be the same as those of epilepsy of early life, fright and trauma playing distinct parts. In all Mendel's cases syphilis was excluded; hence he disputes Seeligmüller's claim that syphilis is to be suspected in all cases of epilepsy occurring after the age of twenty. Arthritis, which Charoot and Delany thought had some relation to *epilepsia tarda*, was never observed. Neither pregnancy nor the menopause seem to have much influence upon *epilepsia tarda*. In a part of the cases the attacks increase in frequency and severity, and the mental faculties deteriorate, just as in the epilepsy of earlier life; but in general the course is milder and not so progressive, and the mental faculties suffer less. The various psychical equivalents, and mental disturbances preceding or following the attacks, or occurring during the intervals, are not infrequently observed, and insistent ideas may be associated with the affection, but this is less common than in the epilepsy of early life. The prognosis and treatment do not differ materially from the prognosis and treatment in ordinary epilepsy.

INFECTIOUS NATURE OF CHOREA.

Pianese¹⁴ has undertaken an elaborate and thorough study of the infectious nature of chorea, and has come to some very important conclusions, which follow:

(1) From the cord of a young girl, who died of an attack of ordinary chorea of a grave and generalized type, he succeeded in isolating a bacillus 2 to 4 μ long and $\frac{1}{2}$ to $\frac{1}{3}$ μ wide, deprived of cilia, and endowed with slow movements. It grows on the ordinary culture media, and takes a characteristic aspect on gelatine. It is sporific, and grows well between 18° and 38° C.; it dies at 60° C. and — 5° C.; it resists rapid dessication for seven days, action of light for thirteen hours.

(2) Inoculations of pure cultures in animals (dogs,

rabbits, guinea-pigs) give positive results when practised in the anterior chamber of the eye, along the nerve sheaths and under the cerebral dura; they are negative if made into the subcutaneous connective tissue, the great visceral cavities or the blood-vessels.

(3) When the inoculations have given positive results the animals have presented a trembling, either general or limited to certain muscular groups (the muscles of the back or shoulder by preference); they become apathetic, timid, frightened at trifles, and they utter piercing cries when the spine is roughly touched. Ordinarily these phenomena appear twenty-four hours after inoculation. At first they are slight, but they increase; contracture develops, walking becomes more and more difficult, and death ensues at the end of five days. Dogs and rabbits inoculated along the sciatic have presented for twenty or thirty days a general trembling, with contracture and emaciation, and then have almost completely recovered.

(4) The organs of the animals who died from these inoculations were also tested; the brain, cord and nerves have always given cultures, but the liver, spleen, etc., have produced nothing.

(5) Inoculations of cultures sterilized in boiling water and in other ways have given the following results on animals; no febrile reaction either immediately after the injection or during the whole time that the animal remained alive; some phenomena resembling those which were presented by animals inoculated with pure cultures; apathy and some weakness for a few days, and then progressive emaciation leading to death after a period of time which varied with the size of the animal.

(6) The bacilli probably travel in the organism of the animals experimented on through the lymphatics.

(7) On a bacteriological examination, bacilli were found only in the cord of choreic cases, and only in the brain, cord and nerves of animals experimented on.

(8) The results of the histological examination in a case of chorea were as follows: marked hyperæmia of the central nervous substance, with numerous punctate hæmorrhages; little foci of inflammation, very limited, peri-vascular, and disseminated in a variable fashion; slight ependymal myelitis; beginning degeneration of the columns of Goll; in the lumbar cord, cellular infiltration in the gray horns, chiefly the anterior; the muscles were fissured, and showed waxy degeneration; marked hyperæmia of the liver and spleen; intracapsular hæmorrhages, cloudy swelling and necrosis of epithelium of the renal tubules; the lungs were dotted with hæmorrhages, and there was some pigment formation. In animals inoculated with pure cultures he found hyperæmia of the whole central nervous substance; pigmentary infiltration of the cells of the anterior and posterior horns of the cord; marked hyperæmia of the spleen; a high degree of hyperæmia of the liver, with very small spots of necrosis; cloudy swelling and necrosis of epithelium of the renal tubules. In animals inoculated with sterile cultures he found the same alteration of the ganglion cells of the cord; a little hyperæmia of the central nervous substance; degeneration, chiefly fatty, of the endothelium of the vessels of the liver; cloudy swelling, vacuolization and necrosis of epithelium of the renal tubules.

In this connection, it will be remembered that Dana,¹⁵ in a case of chorea, found a diplococcus in the deep layers of the pia and the superficial layers of the cerebral cortex.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING October 14, 1893, the President, DR. CHARLES M. GREEN, in the chair.

DR. J. G. BLAKE presented a

REVIEW OF A SUMMER'S WORK IN GYNÆCOLOGY AT THE BOSTON CITY HOSPITAL.¹

In closing, he said he wished to make three points: first, that Alexander's operation did not interfere with pregnancy in any way; second, the value of the conservative as opposed to the radical operation in cancer of the uterus; third, the value of dilatation and drainage as opposed to laparotomy in catarrhal disease of the tubes.

DR. F. H. DAVENPORT said that in regard to the question of the influence of the Alexander operation on pregnancy, he had had no opportunity in his own cases to judge. There were two effects to be feared: one, the termination of pregnancy before full term; the other, the question of the position of the uterus during pregnancy or after its termination. With regard to the first, some statistics of value had been published by a writer on the Continent, which showed that the Alexander operation had very little tendency to interrupt pregnancy, while ventro-fixation, which has been advised as a preferable operation in these cases, did favor abortion. As regards the effect of pregnancy on the subsequent position of the uterus, he had not seen any statements. Within a few days, however, he had seen a woman who had been operated on in the early summer for prolapse of the uterus by the combined operation of perineorrhaphy and Alexander's, who was two or three months pregnant, and in whom the uterus was so prolapsed as to lie half over the vulva. He replaced it in the knee-chest position, and held it back by a pessary. It was not surprising that this should have occurred, for it has been his experience that in not a few cases it is at least six months before the soreness and tenderness about the incision disappears, which seems to show that the ligaments are often as long as that in becoming firmly adherent in their new position. In the present case, pregnancy supervening so soon after the operation, they would be very apt to stretch. As regards the operative treatment of cancer, the question of ultimate results is still so uncertain that very little of value can be deduced from statistics in favor of one operative procedure or another. Within a day or two, Dr. Davenport had seen three statements by German writers as to the per cent. of ultimate cures after operative treatment, which varied from five per cent. to forty per cent., showing either that they had different ideas as to what a definite cure is, or that they restricted their figures to one class of cases. As long as such uncertainty exists in the prognosis it is wise to give the patient every possible chance. Therefore he would advise a radical operation in all cases except the absolutely hopeless, feeling that even if the disease did return, it was robbed of so many disagreeable features that the patient's lot was preferable.

Dr. Davenport said that in his experience, when cancer returned after the removal of the whole organ,

it came back in the broad ligaments, and did not ulcerate through into the vagina. It was therefore unaccompanied by the hæmorrhage and foul discharge which is so distressing both to the patient and her friends, and her condition was very much better than if it had been left alone. He was also convinced that there was less pain.

DR. GEO. HAVEN has recently seen a case of pregnancy following Alexander's operation. The cervix was almost outside the vulva, but the case went on to full term and was delivered without complication. After convalescence he found the uterus subinvolved, but not badly retroverted, and he thinks that she will soon be in good condition. As to relief of epilepsy, spoken of in one case reported by Dr. Blake, he has seen it stated that almost any operation is often curative for a year or so, but the epilepsy is almost sure to return. He agrees with Dr. Davenport in preferring the radical operation for cancer, preferably the supra-pubic one.

DR. EDWARD REYNOLDS has had charge of some six cases of pregnancy referred to him because they had previously had an Alexander operation performed. All went on normally, and in all the uterus returned after the labor to the normal position, so that he would not have known that any operation had been performed. As to dilating and packing, he is of the opinion that good results are obtained when the tubes are straight and there is but one collection of fluid; whereas, if they are tortuous and there is more than one collection of fluid, this operation is a failure. As to cancer of the uterus, the disease is so short and disagreeable that he thought patients would run any risk of escaping by a radical operation, which he would perform as early as possible, especially if the disease was at the fundus.

DR. G. HAVEN said in a case he reported the other night the fundus and cervix were involved, and not the vagina. Here radical measures were very effective, while palliative ones would have been of no avail.

DR. JOHN HOMANS said that in his experience there was little or no pain on recurrence of the disease after a radical operation, while after palliative measures the pain was as marked as ever; and he mentioned two cases which illustrated this.

DR. SINCLAIR spoke of a case where the uterus was removed for cancer. Here a recurrence took place, with great tendency to hæmorrhage, which could be restrained. There was, however, no pain.

DR. DAVENPORT stated that this had also been his experience. With a recurrence after a radical operation there was absence of ulceration and discharge, no odor, rarely hæmorrhage, and much less pain.

DR. CHARLES M. GREEN: I confess that I am yet to be convinced of the wisdom of performing the operation for shortening the round ligaments during the child-bearing period. I have always supposed that the uterus was intended to be a movable organ, free to accommodate itself to a full or empty bladder or rectum, and free to rise and become an abdominal organ in pregnancy. If pregnancy ensues in a uterus raised and held by the Alexander-Adams operation, one of four things must happen:

(1) The uterus will be firmly held and prevented from rising, and miscarriage will occur. It is known that this sometimes happens, although probably less frequently than after ventro-fixation.

(2) The uterus will rise and pull away the shortened ligaments from their stitched attachment to the

¹See page 86 of the Journal.

pillars of the ring. This event would probably not occur if the ligament had been carefully stitched, unless pregnancy ensued very shortly after operation.

(3) The round ligament will stretch as the uterus rises. If the ligament does stretch, what assurance is there that after the lying-in month the uterus will be held in the position to which it was drawn by the Alexander operation? What assurance that the patient will be any better off, in respect to the position of her uterus, than she was before the operation?

(4) The round ligament, which is made up in part of muscular fibres from the thin, superficial, muscular coat of the uterus, will partake with the uterus in the muscular hyperplasia which normally occurs in the first half of pregnancy. If this muscular hyperplasia, this physiological elongation of the round ligament can be shown to take place, then we may expect that the ligament will involute with the uterus, shorten, and, after the lying-in period is over, hold the uterus where it was before pregnancy.

In the absence of positive information on these points, it seems to me that we need the evidence, not of three cases, nor of six, but of many times that number. When it can be shown by a considerable series of cases, observed for some months after the puerperal period, that miscarriage rarely occurs after and in consequence of the Alexander operation, and that the uterus remains in essentially its normal position after puerperal convalescence, my preconceived objections to this operation will disappear; until then I must regard it as unphilosophical from an obstetrical point of view.

DR. BLAKE, in closing, said that he restricted his operations for drainage to cases of catarrhal salpingitis. As regards cancer, in the early stages, he himself had no doubt of the value of hysterectomy; whereas, if the disease had extended, there was no gain to be had by removal of the uterus, and life was endangered by the operation. He preferred the palliative operation in this case, and not to endanger life.

DR. N. F. CHANDLER read by invitation

A REPORT OF TWO PREGNANCIES FOLLOWING A LAPAROTOMY.²

DR. GREEN said that it was an interesting coincidence in this case that in both pregnancies a cervical mucous polypus should have developed, and that the patient should never have had a similar affection at other times. He was not aware that these glandular polypi had any particular relation to pregnancy: they are found in all ages, even in old women. The most interesting feature in the case was the extreme nausea, vomiting and emaciation towards the close of the second pregnancy, and the explanation of these symptoms. When miscarriage occurred between the fourth and fifth months of the first pregnancy, it was thought at the time that the accident was due to adhesions, consequent on the laparotomy for removal of a cyst of the broad ligament, which adhesions prevented the uterus from rising. With this theory in view, the patient was kept very quiet, and much of the time in bed, during the second pregnancy. When, however, the early nausea and vomiting had disappeared, and the uterus had risen above the site of the supposed adhesions, it was hoped that all would go well. When nausea and vomiting supervened later in pregnancy, both Dr. Chandler and Dr. Green were at a loss to account for the symptoms. Great attention had been

paid to diet and hygiene, and there was no fault with the kidneys. Finally, it was found that the fetal head had descended low into the pelvis, apparently because the tension of the abdominal wall, made more rigid by the unyielding cicatrix, afforded more resistance to the enlarging uterus than the girdle of contact at the pelvic brim. The head descended, according to Dr. Green's recollection, a month or six weeks earlier than usual, and it seemed to Dr. Green that the aggravated nausea and vomiting were attributable to the pressure of the head on the cervical and pelvic nerves. It was well known that nausea in the early months was often due to pressure of the enlarged pregnant uterus while it was still a pelvic organ, and that the symptom disappeared when the uterus rose into the abdominal cavity. By analogy, therefore, it seemed reasonable that in a susceptible patient the same symptom might be caused by a premature descent of the head.

DR. J. HOMANS said that the cyst in this case weighed a pound, and was the size of an orange. The tube was long, measuring seven inches; that and the ovary were removed. There were no adhesions, and nothing remarkable about the operation.

DR. EDWARD REYNOLDS suggested that the partial dilatation of the os was a cause of the vomiting.

DR. GREEN presented an obstetric-case blank, which he had prepared as a convenience in recording cases at the bedside. The blank is similar to the one in use at the Boston Lying-in Hospital, some changes having been made to adapt it to the requirements of private practice.

		Para.	Age,	Color,
Birthplace of F.		Occupation,		
Birthplace of M.		General condition,		
Last m.	Quickening,	Labor expected,		
Preceding pregnancies and labors,				
Labor began,		First visit,		
Presentation and position,		Cervix,	Os uteri,	
Fetal heart { rate,		Maternal P., T.,		
location,				
1st stage ended,		Membranes ruptured,		
2d stage ended,		Pulse,	Temperature,	
3d stage ended,		Pulse,	Hæmorrhage,	
Placenta and membranes,		Length of funis,		
Perineum		Duration of labor,		
Child's name,				
Sex,	Weight,	Length,		
Left patient,		Pulse,	Condition,	

The first blank line is intended for the name and address of the husband, the second for the wife's name. Below are spaces for recording the birthplace of both parents, the occupation of the father, and the name and sex of the child: all of these data are needed for the report required by law to be made to the city registrar. There is purposely room for but brief notes on the face of the blank; but on the back may be recorded any points of particular interest in the labor or convalescence. The stereotyped plate for printing these blanks is with Mr. George H. Ellis, 141 Franklin Street, who will furnish the blanks for the cost of printing.

283 WASHINGTON STREET, BOSTON, MASS.****AVOIDABLE RESULTS AND ESSENTIAL
PRECAUTIONS IN VACCINATION.**

DURING the present season, there has been a large amount of vaccination done throughout this State and reports have come to us from numerous quarters concerning the prevalence of vaccine disease, especially among school-children, and the results.

First, the vaccine which has been used is the cow-pox virus obtained from some of the many establishments that now guarantee to physicians a supply of pure animal vaccine. The use of the humanized or Jennerian virus seems to be almost a thing of the past. Nevertheless a few physicians still prefer the humanized virus, one remove from the cow, using for vaccine material the clear lymph of a healthy child, taken about the seventh day; and it has been affirmed that this virus acts more mildly than the animal vaccine, while being equally efficacious in conferring immunity.

With regard to the results of vaccinations, the vaccine disease seems in most cases to have run a fairly typical course, occasionally being of rather severe character. The unusual number of cases of marked general vaccinia eruption is to be accounted for by the unusual number of cases of vaccinia now in the community, and in proportion to the total number of children undergoing vaccination at one time is not probably at all increased. In one school in the vicinity of Boston there were about a hundred children successfully vaccinated (primary vaccination); of this number fifty per cent. continued their attendance at school without any interruption; twenty-five per cent. were obliged to absent themselves from school for a few days only, while the other twenty-five per cent. were confined to their homes for more than a week.

A physician living in one of the cities on the coast writes us that in his locality there have been an unusual number of severe cases of vaccine disease. He has never before seen so many "bad arms," and some children have been very sick. All the physicians in that vicinity have used virus obtained from the — Vaccinal Institute. He has observed from the twelfth day

intense inflammatory oedema develop around the point of vaccination, then lymphangitis and cellulitis, fever and other general symptoms of a septicæmic character, finally an extensive cutaneous necrosis in the region of the vaccination. In one instance (in which about the whole city was interested) he despaired of the life of his patient; fortunately the child is now recovering, but with a large slough at the point of vaccination. He believes that in this, as in other similar but not so violent cases, there was a complication of erysipelas due to the introduction of the streptococcus by scratching. Other physicians in the same locality have had cases of a similar nature, and it has been believed that the vaccine obtained on a certain occasion from — farm was of a particularly virulent nature. The cellulitis, erysipelas or lymphangitis which have caused such dire alarm and opposition to vaccination are to be explained by the same principles as under any other surgical operations; some contamination of the wound by micro-organisms. In vaccination the physician has not a complete control of the whole chain of asepsis; he must trust to the honesty and cleanliness of the vaccine establishment, which should be above suspicion.

Our correspondent writes that the ivory points in those packages were stained *red*, as if from admixture of blood; this certainly indicates that sufficient care was not taken in charging the points.

These facts show that the owners of vaccine establishments have a responsibility to physicians and to the public of which they cannot be too mindful. They are expected to furnish vaccine of unexceptionable quality; obtained from healthy heifers, at just the right time, and under conditions of perfect cleanliness and asepsis. The lymph which is furnished, should be clear lymph, not lymph and blood or pus.

Physicians, too, have a responsibility in every case of vaccination, and this little operation should not be performed in a hasty and slovenly manner. Though antiseptics may not be used during the operation, as likely to interfere with the result which is sought, yet vaccination should be performed with perfectly clean instruments, and aseptically. The scarification may be made with the ivory points themselves, or with a fresh needle for each case, which in addition may be passed through an alcohol flame. Some physicians wisely make a practice of washing the arm before vaccination. All should do so. The same point should never be used on two patients: we fear this has been done, though very exceptionally.

What shall be done with the vaccinated arm? Some apply immediately after the operation a little isinglass plaster over the abraded surface, the vaccine being allowed to dry in, and the plaster having previously been dipped in boiling water. The piece of plaster is taken off next day, and the arm covered with some antiseptic dressing, such as carbolic gauze. This might be expected to be sufficient to protect the vaccine sore from extraneous germs, the gauze being renewed every day. The dried lymph may be covered by aseptic

gauze or cotton glued to the arm at the edge with collodion.

We know physicians who take these precautions every time they perform vaccination. It would probably be better that all should. The vaccinated person is provided with a roll of antiseptic gauze for daily dressings, according to the strict directions of the physician. In this way, the danger that foreign microbes (staphylococci, streptococci, etc.) may enter the solutions of continuity caused by the vaccine disease, and thus add to this disease the evils of microbial associations—and we well know how much in some diseases, as diphtheria, the original virulence is intensified by such associations—this danger, we repeat, is thus likely to be reduced to a minimum.

It might be better that vaccine farms should be established and managed by the State, the points being sold at cost or furnished free. Such a proposition is at present under consideration in this State. Where there is a good State Board of Health, a proper supervision for such a farm or farms already exists.

THE ARMY MEDICAL SCHOOL AT WASHINGTON.

It is always easy to find some matter of special interest in the Report of the Surgeon-General. This year, one of the first subjects to attract attention is the Army Medical School authorized by a General Order of June 24, 1893. Its object is the further instruction of newly-appointed medical officers. Severe as the ordeal of the Army Examining Board may be, the successful candidate has still much to learn before he is fitted to thoroughly perform his duties. In the words of the Report, "Certain of these duties are more important than the clinical treatment of individual cases of disease and injury, because the efficiency of a command may depend upon their proper performance."

The number of questions of practical sanitation on which the medical officers of the army must be well informed are numerous,—matters of site and soil; of ventilation, heating and drainage; of sewerage and the disposal of garbage; of water-supply; of food, slaughtering and storage; of disinfectants; of bacteria and ptomaines. Few recent graduates of our medical schools can be supposed to have thorough knowledge of such subjects, and it is to furnish such post-graduate instruction, as it would be called in civil life, that the Army Medical School is established.

The school is situated at Washington, and its course of instruction will extend over four months, beginning annually on the first day of November. The faculty consists of a president, who will deliver lectures on the duties of medical officers in peace and war; a professor of military surgery, including the care and transportation of the wounded; a professor of military hygiene, including practical instruction in the examination of water, air, food and clothing from the sanitary point of view; and a professor of clinical and

sanitary microscopy, including bacteriology and urinalogy. Truly, the young army surgeon will not find any encouragement to idleness in the first four months of his service.

One of the companies of instruction of the Hospital Corps is also stationed at Washington, and its presence there is of value in connection with the work of the school. The Army Medical Museum and the library of the Surgeon-General's Office cannot fail to be also of service. The direct value of such instruction will be evident at once to any one familiar with the experiences of the late war.

The question naturally arises whether the medical schools of the country furnish to civilians equal opportunities for becoming skilled sanitarians.

There is also a suggestion for the volunteer forces, for it is hinted that the medical departments of two States were not so fully prepared for actual work when the emergency arose as they should have been.

MEDICAL NOTES.

INFLUENZA AMONG THE PINE RIDGE INDIANS.—The influenza has been epidemic and exceedingly fatal among the Indians at the Pine Ridge Agency during the last month. The Indians are poorly protected against the cold weather, and are often sick but a day or so before they die.

A NARROW ESCAPE FROM BURIAL ALIVE.—A town councillor of Barton-on-Trent in England had a narrow escape from burial alive last week. At the very last moment, during the committal service in the cemetery, a friend detected what he thought was a sign of life. On examination the man was found to be still breathing, and was carried home.

DELEGATES TO THE INTERNATIONAL SANITARY CONFERENCE.—Dr. Edward O. Shakespeare of Philadelphia, Dr. Stephen Smith of New York and Dr. Preston H. Bailhache of the Marine Hospital, are the delegates appointed by the President to represent the United States at the international sanitary conference which meets in Paris to-day.

THE QUARCENARY OF PARACELSUS.—The four-hundredth anniversary of the birth of the famous Theophrastus Paracelsus von Hohenheim, at one time Professor of Medicine at Basle, was celebrated the 26th of last November by the villagers of his native place, Maria-Einsiedeln in Switzerland.

THE HUSBAND'S LIABILITY FOR THE WIFE'S MEDICAL EXPENSES.—The Supreme Court of California recently ruled that where the husband is liable for his wife's support, the wife's estate cannot be charged for medical services, medicines and nursing which he secured for her in her last sickness, but that he alone is liable for them.

TYPHOID FEVER ON A WARSHIP.—A warship is a rather unusual place for an epidemic of typhoid fever to occur in; but over thirty of the crew of the British

warship *Canada*, have been sent to the hospitals at Bermuda or Barbadoes. The admiral has requested that the vessel be ordered home at once before the whole crew gives out. It would be interesting, and in such a case probably not difficult, to trace the infection. So far no explanation has been published.

SMALL-POX ON A NEW YORK STEAMER.—The Ward-line steamer *Seguranca*, which sailed a fortnight ago from New York, has been quarantined at Vera Cruz with twenty-two cases of small-pox on board. It is thought that the disease was brought on board at Havana by some steerage passengers.

"VARIOLIN" AGAIN.—The use of "variolin" for the internal administration of vaccination has been sanctioned, it is said, in Brooklyn by the principals of some of the public schools, who have accepted certificates of treatment by this means as a substitute for the required certificate of vaccination.

A FOUR YEARS' COURSE AT THE NATIONAL MEDICAL COLLEGE.—At a meeting of the Faculty of the Medical Department of Columbian University, of Washington, D. C., held on April 11, 1893, it was unanimously agreed to make a four-year course of study necessary before graduation. This measure went into operation at the beginning of the present session of 1893-94. Each of the four courses covers seven months of lectures.

BOSTON AND NEW ENGLAND.

THE NEW CREMATORY AT BOSTON.—There have been already six bodies cremated at the new crematory at Forest Hills this year, and several engagements are made for the next week or two. The possibility of being cremated in New England has apparently increased the interest in this means of disposal of the dead.

SMALL-POX IN BOSTON.—During the week ending at noon on Wednesday, January 24th, there were four new cases of small-pox. There have been no deaths during the week, although one of the last patients, a woman, is critically ill. There are now in the hospital fifteen patients, five of whom are convalescing. Since the first case on October 30th there have been thirty-six cases and seven deaths.

DEATHS AT BOSTON FIRES.—The records of the Boston Fire Department show that there were twenty-six deaths at fires in 1893. Only one of those was of a fireman, a ladderman who was crushed between his truck and an electric-light pole while on the way to a fire.

SMALL-POX IN MASSACHUSETTS.—There have been reported to the State Board of Health since the 21st of last September, when the first case occurred, nineteen cases of small-pox from places outside of Boston. Of these seven occurred in Lowell, four in Holyoke, two each in Worcester and Methuen, and one each in Somerville, Brookline, Marlborough and Yarmouth.

VACCINATION AT NEWTON.—The free vaccination stations in Newton were reopened for three days last week; and 729 persons were vaccinated, which is about twice as many as previously registered.

THE NEWTON HOSPITAL.—At the annual meeting of the Corporation of the Newton Cottage Hospital, held last week, it was unanimously voted to change the name of the institution and corporation from Newton Cottage Hospital to the Newton Hospital. The annual reports showed an increase of thirty-two per cent. in the number of patients during the past year, and that the new wards for contagious diseases had not been vacant at any time during the year. A nurses' home has also been completed.

DIPHTHERIA AT CALAIS, VT.—So many cases of diphtheria have occurred at Calais, Vt., the last ten days that three of the schools have been closed for the present.

DIPHTHERIA IN GRANBY, CONN.—There is a considerable epidemic of diphtheria at present in Granby, Conn., so that the county health-officer has ordered the schools closed.

SMALL-POX IN WINSTED, CONN.—Several cases of small-pox, some fatal, have occurred the last week at Winsted, Conn.

THE NEW HAMPSHIRE STATE INSANE ASYLUM.—The annual report of the Superintendent of the New Hampshire State Insane Asylum shows that during 1893 there were 248 men and 60 women under treatment in the hospital. The mortality rate during the year was 7.2 per cent. The percentage of recoveries, based upon the number of cases admitted, and excluding all recoveries from opium or alcohol habits, was 25.80 per cent.

NEW YORK.

MORTALITY.—During the week ending January 20th the number of deaths reported in this city was 888, as against 929 the previous week, which latter mortality was 103 less than the average of the corresponding weeks for the past five years. The deaths from influenza were 18, which was an increase of 3 over the week ending January 13th; but the deaths from pneumonia, 150, were 16 less. There were 6 deaths from small-pox, against 8 the previous week, and there was a slight increase in the mortality from diphtheria and typhoid fever.

ANNUAL MEETING NEW YORK COUNTY MEDICAL ASSOCIATION.—The annual meeting of the New York County Medical Association was held on January 15th, and the attendance was the largest in the history of the Association, about 300 members being present. The report of the Corresponding and Statistical Secretary, Dr. A. D. Ruggles, showed that during the past year 121 new members had been elected, and that the Association had lost 14 members by death and 27 from other causes. The total membership is now 951. The following officers were elected: President, Dr. S. B. Wylie McLeod (re-elected); Vice-

President, Dr. Augustus D. Ruggles; Recording Secretary, Dr. P. Brynberg Porter (re-elected); Corresponding and Statistical Secretary, Dr. Wm. W. Van Arsdale; Treasurer, Dr. John H. Hinton (re-elected); Member of the Executive Committee, Dr. John Blake White.

OUTBREAK OF SMALL-POX AT CHARITY HOSPITAL.—A serious outbreak of small-pox has occurred at Charity Hospital, and the history of it is of more than ordinary interest. On January 9th, Dr. Henry M. Silver, Demonstrator of Anatomy at Bellevue Hospital Medical College, was about to give a lecture before a class of students at that college, and on removing the cloth from the subject on which he was to give his demonstration in the anatomical room adjoining the amphitheatre, he was astounded to find the corpse covered with the pustules of small-pox. He at once notified the Bureau of Contagious Diseases; the building was disinfected, and about 125 students were vaccinated. On inquiry, it was found that the body which had recently been received from Charity Hospital was that of Louis Schmidt, sixty-three years of age. It seems that in the latter part of December Schmidt was taken from a lodging-house in East Broadway to Gouverneur Hospital, suffering from malignant syphilis. Whether small-pox had also developed at this time has not transpired; but, at all events, the latter disease was not diagnosticated by the physicians in charge, and on December 26th he was sent to the reception ward of Bellevue Hospital. Here the examining physicians confirmed the diagnosis of syphilis, and on the following day he was sent to Charity Hospital and admitted to the syphilitic wards. The man continued to grow worse, and on January 2d he died. It still being believed that he had suffered only from syphilis, the body was removed to the city morgue, where it was kept for nearly a week, that friends might have the opportunity of claiming it. Then it was taken to Bellevue College and placed among the subjects for dissection; and it was not until January 9th, as mentioned, that the real cause of death was discovered by Dr. Silver. The correctness of his diagnosis has now been abundantly attested. On January 16th three cases of small-pox developed in the male wards of Charity Hospital, and the patients were at once sent to North Brother Island. That evening Dr. Doty, Chief Inspector for Contagious Diseases, sent four of his corps to Charity Hospital, who vaccinated over eight hundred persons—patients, physicians, nurses and servants—and the whole institution was placed in strict quarantine. On January 18th seven additional cases of small-pox developed, and among those attacked with the disease was the warden of the hospital, Mr. Roberts. They were all removed to the hospital for contagious diseases on North Brother Island. On the same day a case of small-pox was reported at the Florence Mission for Fallen Women on Bleecker Street, and an investigation showed that the patient, a young woman twenty-two years of age, had recently been discharged from

the work-house on Blackwell's Island. While serving a term of imprisonment there she had been detailed as a scrub-woman in Charity Hospital, and it was while she was engaged in cleaning the ward where Schmidt was lying that she contracted the disease. The Florence Mission, which has about thirty inmates, has also been placed in quarantine for three weeks.

Miscellany.

TO ABOLISH THE OFFICE OF CORONER.

THE following is an abstract of recommendations contained in the memorial of the select committee of the Medico-Legal Society of New York, addressed to the Legislature of the State and dated January 10, 1894:

Your memorialists, after duly considering the premises, unanimously recommend to your honorable body that you amend the existing statutes, regulating the powers, duties, and compensation of coroners

(a) By creating a new officer to be styled "Medical Examiner," as in Massachusetts and Connecticut; or "County Physician," as in New Jersey, who shall be authorized to conduct inquests or examinations in all cases where death has occurred by violence, or there is reason to suspect that the same is due to other than natural causes, having charge of all autopsies and all questions on the medical side of the inquiry, without a jury before a competent court, or before the coroner as a judicial officer, if retained after the plan adopted in Connecticut.

(b) That said medical examiner be appointed by the county judges of each county, except New York, and by the Chief Justice of the Court of Common Pleas in that county, and only physicians skilled in their profession, of at least five years' practice, to be eligible to such appointment, and so far as possible without reference to partisan political considerations.

(c) That only persons learned in the law shall be eligible to the office of coroner, and that if the inquiry is conducted before the coroner, he shall have charge judicially of all legal questions, and that the hearing, inquest, and proceedings shall be the same as if before the Police Magistrate in the City of New York or other cities of over 100,000 inhabitants, and before Justices of the Peace in all counties of the State except New York and King's Counties.

CLARE BELL, *Chairman*, THEODORE H. TYNDAL, CHARLES G. GARRISON, WYATT JOHNSON, M.D., ABRAM H. BAILLY, H. W. MITCHELL, M.D., MORITZ ELLINGER.

CHOLERA.

It may be interesting to our readers to read some extracts from a letter from Constantinople written last December. The letter is not from a physician, but from a person having such opportunities for accurate observation as to entitle his account to the readiest acceptance:

"Cholera is said to be increasing. I pity the poor, especially the natives, for they have no protection from the municipal doctors, who seize them on the slightest pretence. One man was reported to be ailing a little. The municipal doctor came, said it was cholera, covered him all over with chloride of lime, wrapped him in a cloth, then smeared that with tar, then injected a solution of phenic acid behind his ears and into his nose. The priest was called, was sprayed with a solution of phenic acid till his robe was soaked

with it, and his beard and hair; then he was told to say the prayers for the dying. Then the man was carried off to the cholera hospital; and the next day word came that he was dead and buried.

"A few days ago, a *hamal* (porter) who had too heavy a load stopped to rest on the bridge—put off his load, put his hands to his sides and gave a groan. Naturally, he looked a little pale. In a moment a crowd gathered; then the police came and carried him to the cholera hospital, in spite of his protestations that it was his heavy load, that he was not sick. In due time his friends heard that he was dead and buried.

"The poor people are frightened, and try to conceal themselves if they are really sick. Doctors generally are having an easy time, for no one likes to have a doctor seen entering his house."

SIR JAMES SIMPSON'S EARLY EXPERIMENTS WITH CHLOROFORM.

SIR JAMES SIMPSON'S daughter has written in the *January Century* an interesting account of the introduction of chloroform in England, and of her father's early experiments in narcotic and anæsthetic drugs. She says:

"Round the table in the well-known dining-room in Dean Terrace it was his custom every evening to have an anæsthetic *séance* with Drs. Keith and Duncan. Each had a glass or saucer from which to inhale the various substances under trial. On the evening of November 4, 1847, on returning home after a weary day's labor, Dr. Simpson and his two friends sat down to their somewhat hazardous work. Having inhaled several substances without effect, it occurred to Dr. Simpson to try a small bottle of chloroform which he had had, he wrote, 'for several days in the house before trying it, as, after seeing it such a heavy and unvolatile-like liquid, I despaired of it, and went on dreaming about others.'

"The tumblers were newly charged, and the inhalers resumed their vocation. Immediately an unwonted hilarity seized the party, which became bright-eyed and very loquacious. Suddenly there was a talk of sounds being heard like those of a cotton-mill; a moment more, then all was quiet; and then a crash. On awakening, Dr. Simpson's first perception was mental: 'This is far stronger and better than ether.' His second was to note that he was prostrate on the floor, and that among the friends about him there was confusion. Hearing a noise, he turned and saw Dr. Duncan beneath a chair; his jaw had dropped, his eyes were staring, his head was bent half under him. He was quite unconscious, and snoring in a most determined manner. More noise still and much motion, and then his eyes overtook Dr. Keith's feet and legs making valorous efforts to overturn the table."

The interest in these experiments was not confined to the master of the house. The butler experimented also—only on the cook. On one occasion, finding some chloric ether in aerated water, he gave a glass of it to the cook, who, drinking it hastily, fell down unconscious. The butler rushed into the dining-room, saying, "For God's sake, sir, come down! I've pushed the cook." After the woman was restored to consciousness the man was chary and contemptuous of any other concoction, and to the end repeated stubbornly his sentiment, "Chlory's the thing."

Correspondence.

FOUR YEARS' COURSE AT RUSH MEDICAL COLLEGE.

RUSH MEDICAL COLLEGE,
MEDICAL DEPARTMENT OF LAKE FOREST UNIVERSITY.
CHICAGO, January 16, 1894.

MR. EDITOR:—My attention was called yesterday to the editorial note following the notice of the four years' course established by this college, published in your last issue.

Replying to your queries, I would say that the required annual course in Rush Medical College is eight months.

Regarding the facilities for completing a four years' course in three years,—there is no possible way whereby any under-graduate could do this; but graduates in pharmacy and dentistry, on account of their previous studies, we think would be well qualified to enter the second year in the Medical College; or graduates from dental colleges or pharmaceutical colleges requiring three full years of study, would be qualified to enter the third year of the Medical College.

Regarding graduates in arts and sciences,—we believe that they would be able to acquire as much information in the second and third years in the college as the ordinary graduate from a high school would be able to acquire in the first, second and third years; therefore, it seems to us only just to allow them this privilege. The fourth year will be the same for all; and it appears to us that it will encourage young men who wish to study medicine to make a better preliminary preparation. The schedules for recitations and lectures to these classes are so arranged that the hours do not conflict.

Hoping that this fully answers the questions which arose in your mind, I am,

Yours very truly,

E. FLETCHER INGALLS, Registrar.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JANUARY 13, 1894.

Cities.	Estimated population for 1892.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from					
				Infectious diseases.	Consumption.	Typhoid fever.	Diphtheria and croup.	Measles.	
New York . . .	1,891,806	929	385	17.28	24.96	1.32	9.00	5.48

Newburyport . . .	14,073	5	0	—	—	—	—	—	
Amesbury . . .	10,920	3	1	66.66	—	—	—	—	

Deaths reported 8,883: under five years of age 1,126; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 406, acute lung diseases 714, consumption 364, diphtheria and croup 190, typhoid fever 44, measles 41, scarlet fever 38, diarrhoeal diseases 29, cerebro-spinal meningitis 24, whooping-cough 16, small-pox 13, erysipelas 7, malarial fever 4.

From scarlet fever New York 9, Chicago 7, Philadelphia 6, Boston 4, Somerville 3, Cambridge and Amesbury 2 each, Brooklyn, Cleveland, Milwaukee, Taunton and Everett 1 each. From diarrhoeal diseases New York 11, Chicago and Philadelphia 4 each, Brooklyn 3, Worcester and Lowell 2 each, Milwaukee, Charleston and Fall River 1 each. From cerebro-spinal meningitis New York 4, Chicago and Lowell 3 each, Cleveland, Pittsfield and Everett 2 each, Philadelphia, Brooklyn, Washington, Worcester, Lynn, New Bedford, Chelsea and Quincy 1 each. From whooping-cough Chicago 6, New York and Brooklyn 3 each, Philadelphia, Boston, Lowell and Taunton 1 each. From small-pox Chicago 8, New York 3, Boston and Lowell 1 each. From erysipelas New York 3, Chicago, Boston, Washington and Malden 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending December 30th, the death-rate was 22.8. Deaths reported 4,481: acute diseases of the respiratory organs (London) 516, whooping-cough 150, diphtheria 101, measles 85, fever 51, scarlet fever 49, diarrhoea 36, small-pox (Birmingham 5, Bristol and Bradford 3 each, Nottingham and Oldham 1 each) 13.

The death-rates ranged from 15.6 in Preston to 49.3 in Plymouth; Birmingham 21.3, Bolton 20.0, Brighton 27.0, Croydon 20.1, Huddersfield 19.2, Leeds 20.6, Leicester 16.7, Liverpool 26.3, London 23.3, Manchester 24.9, Newcastle-on-Tyne 20.4, Norwich 20.5, Portsmouth 17.1, Sheffield 20.0.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending January 6th, the death-rate was 22.8. Deaths reported 4,667; acute diseases of the respiratory organs (London) 566, whooping-cough 166, measles 102, diphtheria 89, scarlet fever 50, fever 43, diarrhoea 32, small-pox (Birmingham 6, Bradford 3, London and Oldham 2 each) 13.

The death-rates ranged from 11.2 in Halifax to 40.3 in Plymouth; Birmingham 24.7, Bolton 16.7, Croydon 15.8, Gateshead 19.0, Hull 23.5, Leeds 16.9, Leicester 15.2, Liverpool 26.0, London 24.5, Manchester 22.6, Newcastle-on-Tyne 19.1, Nottingham 23.3, Portsmouth 17.7, Salford 22.5, Sheffield 17.9, West Ham 25.8.

METEOROLOGICAL RECORD.

For the week ending January 13, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 13, 1894, TO JANUARY 19, 1894.

Leave of absence for one month, on surgeon's certificate of disability, is hereby granted to MAJOR EDWARD B. MOSELEY, surgeon, U. S. A.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 20, 1894.

CLEMENT BIDDLE, surgeon, detached from duty, Marine Rendezvous, Philadelphia, Pa., and await orders, Rendezvous closed.

E. P. STONE, passed assistant surgeon, detached from Marine

Rendezvous, Boston, Mass., and continue on special duty in Boston, Mass.

T. A. BERRYHILL, passed assistant surgeon, authorized to take a course of instruction at the Naval Hospital, Brooklyn, N. Y.

F. J. MILLS BROWNE, medical director, retired, granted two months' leave with permission to go abroad.

SOCIETY NOTICES.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH.—The tenth annual meeting of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn, on Tuesday, May 22, 1894. All Fellows desiring to read papers will please notify

E. H. SQUIBB, M.D., Secretary, P. O. Box 760, Brooklyn.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The eighty-eighth annual meeting of the Medical Society of the State of New York will be held in the City Hall at Albany, on Tuesday, Wednesday and Thursday, February 6th, 7th and 8th. The anniversary address by the President will be given Wednesday evening, February 7th, at 8 P. M. in the Senate Chamber. The annual dinner at the Delavan House at 9.30 P. M.

HERMAN BENDELL, M.D., President.
FREDERIC C. CURTIS, M.D., Secretary, Albany.

APPOINTMENT.

EDWARD JACOB FORSTER, M.D., of Boston, has been appointed Medical Director on the staff of Brigadier-General Bridges.

RECENT DEATH.

J. G. NAVA, M.D., died in New Orleans, La., January 15th, aged sixty years. He was born in Cuba and after graduating from the University of Havana studied dentistry in Philadelphia. He then studied medicine in Paris where he received his degree in 1859. Returning to Cuba he became active in the struggle for the independence of the island and at the close of the war against Spain was obliged to leave the country as a price was set upon his head. He escaped to New Orleans where he has since lived. He was editor of *La Libertad*, a French and Spanish paper published in the interest of Cuban freedom. He was a member of the Academie des Sciences of Paris.

BOOKS AND PAMPHLETS RECEIVED.

The Nerve Theory of Menstruation. By Christopher Martin, M.B., Edin., F.R.C.S., Eng. London. 1893.

The Harvard University Catalogue, 1893-94. Cambridge, Mass.: Published by Harvard University. 1893.

A New Pathology and Treatment of Nervous Catarrh. By Seth Scott Bishop, M.D., Chicago. Reprint. 1893.

Concerning Posture. A New Holder for Sims Speculum. By B. H. Daggett, M.D., Buffalo, N. Y. Reprints. 1893.

Current Fallacies about "Nervous Prostration." Traumatic Neuroses in Court. By Dr. L. Bremer, St. Louis, Mo. Reprints. 1893.

Transactions of the Medical Association of the State of Missouri at the Thirty-sixth Annual Session held at Sedalia, Mo., May, 1893.

The Bacteriological Examination of Water and the Information it has Furnished. By Percy Frankland, Ph.D., B.Sc. (London), F.R.S. Reprint. 1894.

Proceedings of the American Microscopical Society, issued quarterly, Sixteenth Annual Meeting held at Madison, Wis., August 14, 1893. Vol. XV. Washington, D. C.; Judd & Detweiler. 1893.

Syllabus of Lectures on the Practice of Surgery arranged in Conformity with the American Text-book of Surgery. By N. Senn, M.D., Ph.D., LL.D., Chicago. Philadelphia: W. B. Saunders. 1894.

The After-Treatment of Cases of Abdominal Section. By Christopher Martin, M.B. (Edin.), F.R.C.S. (Eng.), Surgeon to the Birmingham and Midland Hospital for Women. London: Simpkin, Marshall, Hamilton Kent & Co. 1894.

OVARICTOMY FOR NERVOUS DISEASE.¹

BY ROBERT T. EDDES, M.D.

I DO not wish to undervalue by a thought the triumphs of that branch of our art which has made such enormous strides within the last three decades. I look upon the introduction of the principles of antiseptics or asepsis in surgery, as the only step forward at all comparable to the discovery of anæsthesia. But there may be, as has been often remarked, some disadvantages connected with the freedom from great risk; and the fact that an operation may be done with much less immediate danger to life than it would have caused twenty years ago, seems to be to some extent looked upon as a sufficient reason for doing it. I have been credibly informed that the removal of the normal ovaries is not a very difficult nor, with a reasonable degree of cleanliness, a very dangerous operation; and the history of its popularity is likely to be of greater interest to the psychologist than to the scientific surgeon who prides himself upon the knowledge and skill involved in or obtained by his operations, rather than upon the mere number of incisions or the array of specimens he can display, like the scalps hanging in the wigwag of the Indian brave.

I trust that the time has passed when normal ovariectomy can decently be urged upon a patient by a surgeon who has simply a desire to "make a record"; but I think that there is still some room for testimony as to the ultimate value of the operation from a standpoint other than that of the surgeon, who is likely to lose sight of the patient as soon as the wound has healed.

I do not pretend now to be an unprejudiced witness, though I was more nearly so a couple of years ago; but I have made up my mind decidedly as to the expediency and justifiability of removing ovaries not seriously diseased for the relief of nervous symptoms not immediately dependent upon them, and among these latter I include the so-called ovarian neuralgia or pain in the ovarian region. I have not, however, in the cases mentioned in this paper, with two exceptions, the interest of having advised either for or against the operation.

It may be admitted, moreover, that my field of observation has not been such as to furnish material for impartial statistics, since, of course, the favorable cases do not demand further treatment. I have taken some pains, however, to follow the history of a number of patients who have undergone the operation, and who have either before or afterwards been inmates of the Adams Nervine Asylum; and a few histories not immediately connected therewith.

CASE I. Miss —, physician, age forty (more or less). No signs of menopause. Had herself never suspected any disease of the pelvic organs. For some years worked very hard and anxiously, starting a dispensary and carrying it on under trying circumstances. She had been unfortunate in her domestic relations, having experienced losses, and ill-treatment of a very aggravated character. In the early summer of 1892, which was very hot, she remained at work until she went into the country to take care of a patient. There she began to lose health, and finally had

a severe fit of some kind, which seems to have been opisthotonic and was attributed by her partly to the strychnine that she was taking as a tonic. It is quite as likely, however, to have been hysterical.

In September she returned to the city, her life being considered in danger; and after three weeks in a private hospital and a consultation of several physicians, one at least of whom was far from an enthusiastic advocate of the operation in general, it was decided to remove the ovaries as a last resort. They were said to have been diseased, but I have no description of any lesion except that a cyst was mentioned. She had also a fibroid, which was not removed. She had had pains in her head and back and a defect in her vision so great as to have been spoken of as blindness. A careful ophthalmological examination revealed no visible changes. These symptoms are said to have improved after the operation, which, in a purely surgical point of view, was eminently successful. She recovered rapidly from its immediate effect, but was depressed, and her sight did not return to any useful extent.

Early in December she came under my observation. Her general condition seemed pretty fair. She had a good appetite, with only occasionally dyspeptic symptoms and usually constipation. She had at times severe pain in the back of the neck, but not often severe headache. At times attacks of "going off," in which she became bewildered and more or less delirious. On one occasion she said hundreds of little imps were saying, "Suicide, suicide," to her. Her mental condition was distinctly childish, and her attention directed almost exclusively to the history of her case, which she kept going over and over with great minuteness. Vision was much impaired. At one time she said she saw only one-half of the objects at which she was looking; but as it appeared on a little closer examination that, at one moment, the side on which she saw was opposed to that which was visible the next, the symptom lost the significance which it might otherwise have had as indicating localized cerebral disease. This mental condition grew no better, but she became more suspicious. She jumped out of a window and broke her arm, and was removed to an insane hospital, where she now is.

In a word, this case is evidently one of severe nervous break-down of the hysterical type, in which the operation, however well meant, has had no beneficial effect whatever.

CASE II. Mrs. —, teacher of music, age thirty. No children. Severe dysmenorrhœa since girlhood. In October, 1890, both ovaries were removed, there being a cyst of the right and adhesions of the left. She improved up to the next February, but entered the asylum in July, remaining until the subsequent June. During this time she gained about seventeen pounds in weight. She menstruated at irregular intervals, and with much suffering, though, as she states, less than she had experienced before. She complained chiefly of weakness, and inability to make any exertion without feeling it greatly. There was no mental affection. She has been heard from at various times, nearly up to the present, as having made no essential improvement.

CASE III. Miss —, age twenty. Was in the asylum in 1881 with severe hysteria and ovarian pain. Was operated on two or three years later. The operation was considered a success surgically, and "so far

¹ Read (in part) to the Dorchester Medical Club and to the Roxbury Society for Medical Improvement.

as nerves were concerned." Became a morphinist. Died two or three years ago.

CASE IV. Mrs. —. In asylum in 1881. Soon after went to a private hospital, where she was operated on. She afterwards brought a suit against the hospital and against the surgeon. Presumably, the surgeon, at least, would not be willing to give a very favorable opinion as to state of her mind from the side of morality.

CASE V. Mrs. —, age thirty-four. At asylum in 1884. Moody soon after operated on. Ovaries not diseased, but badly prolapsed. Is said to have been "in a wretched state of health ever since, a chronic nervous invalid."

CASE VI. Miss —, age thirty. Was in the asylum in 1887. Was operated on a few years later. Was an invalid until she died of an overdose of cocaine. The ovaries were normal. The autopsy revealed nothing abnormal in any part of the body.

CASE VII. Mrs. —. In asylum in 1888. Operated on later. Recent information represents her as a confirmed invalid.

CASE VIII. Miss —, age thirty-seven. Was sick twelve years, "though no one knew it." In asylum in 1889. Had been operated on two months previously, the cirrhotic ovaries and a cyst of the broad ligament having been removed. Acted strangely all the time she was in the asylum. The records show a long list of hypnotics and nervines. Has since grown fleshy, but by no means strong. Still (1892) suffers *pain in region of right ovary*. In December, 1893, she was said to have been very much better during the preceding six or eight months. Has done considerable work.

CASE IX. Miss —, age twenty-nine. Dysmenorrhœa. Both ovaries, "without pathological change," were removed together with the tubes. Came to the asylum to recover from the effects. Took a great deal of morphine. Her physician writes in 1892: "She has gained slowly but steadily for two years. If she gains as much during the next year as she has done during the last, she will be pretty comfortable." She now (1893) has the old menstrual pain twice a month, requiring morphine, and "menstruates occasionally, wasting as much as those who flow the most."

CASE X. Miss —, age twenty-nine. Was in the asylum in 1882 and 1883. After an absence of nine months she returned to the same, minus her ovaries. The ovaries were enlarged and imbedded in inflammatory exudation. Nervous and hysterical, saying that she had a misplaced womb. Pains in back and bladder. Menstruated. For several years was unable to work, but at last accounts was teaching in the South.

CASE XI. Mrs. —, age forty. In the asylum in 1884. Overwork, neurasthenia, irregular menstruation, dysmenorrhœa. "Both ovaries were removed in 1885. They were much enlarged and badly diseased. The results of the operation were good, and she has since been in a fair condition of health. For the past five years she has had charge of the management of some kind of institution for ladies."

CASE XII. Miss —, age twenty-seven. Was in the asylum in 1888, nervously prostrated, with no organic trouble. In 1892, having had her ovaries (which were cystic, hard and adherent) removed two years previously, she applied for readmission having been of late profoundly neurasthenic and losing flesh

rapidly. In 1893 her "symptoms had somewhat diminished in intensity by operation, but the character of them had not been changed, except that the abdominal pain of which she complained so bitterly is now a factor of little importance."

CASE XIII. In 1892 application was made for the admission of a married woman, age thirty-four, with neurasthenia and adynamia for more than a year. Her uterine appendages were extirpated a little more than two years before, with "improvement in some directions."

CASE XIV. Another applicant (married, age forty-three) has lately had her ovaries removed, and is now suffering from the shock of the operation.

CASE XV. Another application from a patient who had had the uterus and ovaries removed. Was probably in a condition of incipient melancholia.

CASE XVI. Mrs. —, age thirty-seven. Was at the asylum in 1888, a few months after having had her ovaries and tubes removed. There had been a long history of pelvic inflammation, and the organs were diseased and adherent. She never fully recovered from the nervous shock, but some of the symptoms were slightly relieved by the operation. At the time of her entry, her physician stated that she had been suffering many of the ills of the change of life. She herself said in September that she had had pelvic peritonitis three times since April.

CASE XVII. Miss —, age thirty-three. Was in the asylum in 1890, with neurasthenia, depression, headache, spinal tenderness and too frequent but scanty menstruation. Her cystic ovaries were removed; and her physician states that she is not much improved as to her neurasthenia, perhaps a little. Certain local symptoms are better.

CASE XVIII. Miss —, age thirty. Never well since seven. Lost eyesight at that time. Diphtheria with paralysis at the age of fourteen. A cyst of one ovary removed four years ago, the other ovary one year ago. Uterus stitched to the abdominal wall. She now enters the asylum for neurasthenia, and has made little, if any, improvement.

CASE XIX. Mrs. —, age forty. Invalid for nine years. Nervous at menstrual epochs. Apparently some metritis. Discharged from Adams Nervine Asylum somewhat benefited. After remaining in bed for more than three years longer, her healthy ovaries were removed. "She made an uneventful recovery from the operation; and since then she has been a well woman," doing her own work, making calls and so on.

CASE XX. Miss —, age twenty-nine. Severe dysmenorrhœa and hysteria. Dilatation of cervix without relief. Remained in the Adams Asylum over ten months. Upon her own decision both ovaries were removed on November 2d. They showed some degree of cystic degeneration. There was no local trouble afterward; but she fell into a condition of "stuporous melancholia," and died on November 9th. The autopsy showed absolutely nothing abnormal.²

CASES NOT OPERATED ON.

CASE A. Mrs. —. Four children. An anxious mother, nervous, with profuse menstruation amounting nearly to menorrhagia. She was seen by a physi-

² Since the MS. of the above left my hands, another case has applied, both of whose diseased ovaries were removed in October of November. "She does not rally from the operation . . . and in my opinion a few weeks of rest and freedom from care will enable her again to become self supporting." Would that our experience enabled us to share in her physician's hopeful view!

cian (who now figures as Case I on my list), who, with another lady called in consultation, was anxious for the operation. Mrs. —, at my request, visited another well-known surgeon, who, without absolutely declining the operation, spoke so doubtfully of its probable benefits that she concluded to wait. In the mean time circumstances having prevented anything from being done immediately, nothing was done at all. She now for some reason or other, perhaps from a dearth of medical attendance, for a portion of which I was responsible, is very much better, and retains all her pelvic viscera.

CASE B. Miss —, age thirty-six. Chronic intestinal catarrh for eight years. Abdominal neuralgia for six years. Tingling, numbness, and pain all over body, but especially in extremities. At the urgent request of the patient and somewhat against his own judgment, an abdominal incision was made by a well-known gynecologist; and nothing wrong being found, with praiseworthy self-denial, he declined to remove anything. The moral effect boasted of in these cases did not ensue; but a new anxiety was added to the former symptoms, that is, that adhesions might have taken place which were the cause of the additional pains, now constantly located in the neighborhood of the incision, which she was willing to have repeated on the chance of relief.

CASE C. Mrs. —, age thirty-one. Two children. Has suffered much at the hands of the general practitioner and gynecologist. Entered the asylum with severe abdominal pains. A tumor of a Fallopian tube had been diagnosed and an operation planned. In the absence of the first surgeon, and (on account of fever) the operation being considered urgent, it was done by another. Nothing whatever was found in the tube. The second surgeon told me that he thought it more probable that there had been an accumulation of serum which had escaped into the abdominal cavity (there having been no gush from the uterus) than that the first surgeon had been mistaken in his diagnosis. This is a point on which there appears to me to be room for two opinions. After recovery from this operation the pains remained as before. A year after much better.

These cases were collected with the object of throwing light upon this operation solely from a neurological point of view. The removal of the pelvic organs for surgical reasons is an entirely different matter, although, of course, there may be cases which involve both. I believe that in these the surgical considerations should predominate; and in proportion as nervous symptoms can be clearly shown to depend upon definite lesions of a character which are not likely to recover without an operation, just so increases the justifiability thereof. Unfortunately, we cannot say so much for the prospect of a cure. There are two, possibly more, cases in this list of this character (Nos. X and XVI). For others, where the ovaries are healthy, or nearly so, as far as can be ascertained without removing them, the operation finds but little support from this series, which is to be regarded, however, as consisting of illustrations rather than as making an important addition to statistics already perhaps sufficiently numerous and decisive. The list of five thus marked furnishes the only complete and decisive recovery apparently due to the operation (No. XIX), one invalid still suffering from dysmenorrhœa, one death from cocaine, one death from

the operation, and one case of apparently hopeless insanity. The nine cases in the second and third columns give eight invalids, one of whom is able to do a little work, and one teaching after some further years of invalidism.

It would have been easy to add dozens if not hundreds of cases from the literature of the last few years; but the truth is not to be sought in the reports of operations called "successful" because the wound has closed without unfavorable local conditions. Then, indeed, they do appear in a more favorable guise, being discharged perhaps as "needing only rest and feeding" to complete the cure, until they are again found in the beds of hospital after hospital or doomed for years, if not for life, to the reclining-chair of the chronic invalid.

SUMMARY OF CASES OPERATED ON.

Cases.	Normal Slightly Cystic.	Cystic and Indurated.	Old Inflammatory Adhesions.	Unknown.	Results.
1	×				Insane.
2		×			Chronic invalid. Menstruated with pain (two years ago).
3			×		Died after some years of invalidism of chronic morphia, pulmonary tuberculosis, and necrosis of spine from an accident.
4			×		?
5		×			Chronic invalid.
6	×				Chronic invalid. Death by cocaine.
7			×		Chronic invalid.
8		×			Chronic invalid.
9	×				Invalid. Improving slowly. Menstruates with pain.
10			×		Invalid some years. Now teaching.
11				×	Fair health.
12		×			Invalid. Does some work.
13				×	Invalid.
14				×	Invalid.
15				×	Melancholia?
16			×		Invalid.
17		×			Invalid.
18		×			Invalid.
19	×				Well woman.
20	×				Died a week after operation.

REMARKS ON DIPHTHERIA.¹

BY J. H. MCCOLLUM, M.D., BOSTON.

THE marked prevalence of diphtheria in this city is sufficient reason for an investigation of the prevalence of mild cases of the disease, which are not recognized, and which, therefore, become sources of infection. It is a well-recognized fact that a mild case of any infectious disease is a greater source of danger to the public health than the severer cases. There are many instances in which the local manifestations of diphtheria are so slight that it is impossible to arrive at a positive diagnosis without a bacteriological investigation.

Since 1878, when there were 1,370 cases, the fre-

¹ Read at the meeting of the Boston Society for Medical Observation, November 6, 1893.

quency of the disease has varied from 1,814 cases in 1889 to 831 cases in 1891. The greatest number of cases reported was in 1889, when the number reached 1,814, with 564 deaths. The smallest number of cases was in 1891, when the number was 831, with 282 deaths. Last year, 1892, the number of cases was considerably greater, being 1,353, with 414 deaths. The percentage of deaths to the number of reported cases since 1878 has ranged from 35.7 to 26.44. For the decade from 1883 to 1892, the average percentage to the number of cases has been 29.42.

An analysis of twenty-five of the principal causes of death in this city for 1892 shows that diphtheria is the seventh on the list; and this comparative frequency, with certain slight variations, has existed for the past ten years. In other words, diphtheria causes more deaths than any of the other infectious diseases. For the last ten years, ending with 1892, the percentage of deaths from this disease to the total mortality has ranged from 5.50 in 1889 to 2.19 in 1891, with an average for the same period of 3.82. A study of the cases reported, by months, for the past five years shows that in the summer months, during vacation time, there is a marked diminution in the frequency of the disease as compared with term time. An analysis of the ratio of cases of diphtheria to the thousand of population in each ward of the city, for the five years from 1888 to 1892, shows that neither elevation above mean low water nor a crowded condition of a locality are important factors in causing the prevalence of the disease.

In view of the fact that diphtheria is so much more prevalent when the public schools are in session, and also that situation with reference to tide level and a crowded condition of a locality do not have any marked influence on the frequency of the disease, it is evident that contagion from the mild and unrecognized attacks is a potent factor in causing its spread.

With a view of discovering the actual number of mild cases, Professor H. C. Ernst has instituted a series of bacteriological investigations. It is now universally conceded that the Klebs-Löffler bacillus is the cause of diphtheria, and that by suitable methods of observation it can always be demonstrated by a microscopical examination of cultures from the false membrane found on mucous surfaces. The importance of these investigations, not only to the well-being of the public, but also to the advancement of medical science, cannot be overestimated. The investigation of severe cases of sore throat has been carried on in a great many instances; but the investigation of mild cases, such as are more likely to occur in private practice, has not been conducted to any considerable extent. While it may be said that a bacillus morphologically similar to the Klebs-Löffler bacillus has been found in the throats of persons apparently well, yet this bacillus cannot materially affect the correctness of the diagnosis any more than can the Deneke cheese spirillum affect the accuracy of bacteriological examinations in cases of cholera, for it is now generally conceded by the best observers that this bacillus is an attenuated form of the Klebs-Löffler bacillus, and differs from it only in virulence.

The case which is to be used in the investigations offered you by the Bacteriological Department of the Harvard Medical School contains two test-tubes partially filled with blood-serum, two platinum needles, two cover-glasses and labels. The tubes are to be inoculated at the bedside of the patient by taking a small

portion of the false membrane on the point of one of the platinum needles and making one distinct streak on the right of the culture medium, one in the centre, and one on the left. The object of this is to get the necessary amount of dilution, so that the streak on the left may have distinct colonies, which may be easily isolated for the purpose of microscopical examination. A small portion of the membrane should also be placed in the centre of one of the cover-glasses. The other cover-glass should be placed upon it, and the two rubbed together for a few moments, in order to render the layer as thin as possible. The cover-glasses should then be separated and allowed to dry in the air for a few minutes. They should then be placed with their smeared sides together, put in the paper box in the case, which, with the inoculated tubes, should be sent to the laboratory, where the tubes will be placed in the incubator for twenty-four hours. At the end of that time, if the inoculation has been successful, a growth having the form of minute, rounded colonies, or of larger white colonies, will be evident.

Cover-glasses are made from these growths by staining with Löffler's solution; and these, together with the cover-glasses prepared at the bedside of the patient, stained in a similar manner, are examined by the microscope. If the Klebs-Löffler bacillus is found it is evident that the case is one of diphtheria, and the requisite treatment can be adopted and the proper amount of isolation enforced. If, on the other hand, small, round organisms, known as cocci, are seen under the microscope, it is evident that the patient is suffering from tonsillitis or from some other form of non-infectious throat disease. To those of us who have so many times been in doubt regarding the nature of the disease of the throat in mild cases, these bacteriological investigations will be of great value. If it were possible to carry out these investigations in the public schools, while we might not hope to absolutely stamp out the diphtheria, it is perfectly evident to any one who has studied the subject that the disease would be diminished in frequency to a marked degree.

A second object of this investigation, which is in a measure dependent upon the first, is to show how many cases there are of diphtheria associated with scarlet fever. This is of interest not only from a scientific point of view, but also is of importance regarding prognosis and treatment. A similar remark is true regarding diphtheria and measles. In many cases it is absolutely impossible, without a bacteriological investigation, to say definitely that a false membrane appearing in the throat in the course of scarlet fever and of measles is caused by the presence of the Klebs-Löffler bacillus, or is due to some change caused by the poison of scarlet fever and of measles.

A third object, although not directly connected with mild cases of sore throat, but of great scientific interest, is to show whether the false membrane that is observed in cases of puerperal septicemia is a true diphtheritic membrane, or whether it is caused by other organisms.

In Bulletin No. 4 of the Harvard Medical School Association, in an extremely valuable article on diphtheria, Dr. A. L. Mason says that of the 759 cases admitted to the City Hospital from July, 1890, to January, 1893, 113 cases of non-diphtheritic tonsillitis and laryngitis were sent to the City Hospital as diphtheria, or about 15 per cent. It must be borne in mind, however, that these were severe cases, in which the diag-

nosis, although difficult and in many cases impossible without a bacteriological examination, do not present such a difficult problem as do the milder cases, which, as a rule, are not sent to the hospital. This is only another argument in support of the importance of the proposed investigation which has been explained in detail.

Abbott, in 1891, published the result of his bacteriological investigations in 53 cases of mild sore throat. Of these 53 patients, 9 were found to be suffering from acute pharyngitis, 14 from acute follicular tonsillitis, 8 from ordinary post-nasal catarrh, 2 from simple enlarged tonsils, 15 from chronic pharyngitis, 1 from sub-acute laryngitis, 1 from chronic laryngitis, 1 from rhinitis, and 2 from an affection of the tonsils and pharynx. In only 4 of the 53 cases was an organism found that resembled the Klebs-Löffler bacillus. This investigation is of great interest as showing that the pseudo-diphtheritic bacillus is not a great source of error.

A word might be said regarding the degree of isolation in a case of diphtheria. Although the disease is contagious to a certain extent, it is not nearly so contagious as scarlet fever and small-pox in the unvaccinated. Actual contact with the patient or with the discharges from the mouth and nose are necessary in order to contract diphtheria. Provided that a person does not enter the room of the patient, or does not come in contact with clothing, linen and more particularly handkerchiefs soiled by the discharges, there is very little danger of contracting the disease. Dr. Mason says, in the article to which allusion has been made, that of the twenty-three cases admitted to the diphtheria ward and recorded as doubtful, although isolation was only limited, not one of the number contracted the disease.

In the *Philadelphia Medical News* of December 10, 1892, Wyatt Johnston, of Montreal, has suggested a ready method for the diagnosis of diphtheria. It consists in boiling an egg hard, and then chipping off a small portion of the shell, which, of course, lays bare the albuminous portion of the egg. This exposed surface can then be inoculated with a portion of the false membrane from the throat. The egg can then be inverted in an ordinary egg-glass and put in a warm place over night. If the inoculation has been successful there will be a growth on the exposed surface of the egg, which can be examined by the usual methods. The only objection to this method is the fact that the sterilization cannot be so effective as when tubes of blood-serum, properly prepared, are used; but this remark is not intended to militate in the slightest degree against the value of this device in those cases where it is impossible to obtain other culture media.

The bacillus of diphtheria may retain its vitality for months. Recent experiments prove that the dried diphtheritic membrane in small fragments has retained its vitality for nine weeks, and in larger fragments for from twelve to fourteen weeks. Welch and Abbott, from their investigations, have found that the thermal death-point of this organism is 58° C., 138° F. Löffler previously found that this bacillus did not survive exposure half an hour to 60° C.

With regard to the use of disinfectants, the experiments of Boer prove that in bouillon cultures of the diphtheria bacillus twenty-four hours old, after an exposure of two hours in a solution of carbolic acid, one part to three hundred, this organism was killed.

Recent experiments show that a solution of the mercuric chloride, one part to a thousand, and an exposure for half an hour, caused the death of this organism.

It has been attempted in this brief paper to outline the method of this investigation, and also to call the attention of the members of this Society to its importance. As the number of cases examined thus far has been small, no definite results have been reached, except in individual instances.

A CASE OF MULTIPLE RUPTURE OF INTERNAL ORGANS PRODUCED BY A FALL.¹

BY W. T. COUNCILMAN, M.D.,

Pathologist to the Boston City Hospital; Shattuck Professor Pathological Anatomy, Harvard University.

THE patient, a laborer, was brought into the hospital for injuries sustained in a fall from a roof. There had been a very severe snow-storm and the man had been engaged in cleaning off the snow from a roof. He fell to the ground, bringing with him a large amount of snow. The height of the roof was somewhat under twenty-five feet. No previous history could be obtained from the men who brought him in. On physical examination the pulse was weak and somewhat fluttering. Pupils of equal size. Knee-jerk increased. The man was very noisy and hyperæsthetic. No definite external bruise could be seen, and no localized tenderness was made out. A few hours later the man became quiet and unconscious. The next day the patient was still unconscious; the diagnosis was made of right meningeal hæmorrhage, and a button of bone taken out. There was a considerable escape of clear, watery fluid from the opening. No hæmorrhage to be made out. The pulse was very weak at the time of operation, and numerous subcutaneous injections of brandy and digitalis were given. The pulse became somewhat stronger. Later the pulse gradually grew weaker, respiration became slower and slower, and death took place at 6.30 P. M., thirty hours after the injury. After death information was obtained from a friend of the man that he had been previously subject to periods of insanity, which in some cases were of a violent character.

AUTOPSY (TWENTY-FOUR HOURS AFTER DEATH).

The body is that of a large, strongly-built, muscular man. On the right side of the head there is a crescentic-shaped incision, commencing close behind the left ear and extending upwards and forwards, terminating over upper portion of the frontal bone. On the posterior surface of the thorax on the right side there is a large, subcutaneous hæmorrhage, evidently due to contusion. No evidence of injury elsewhere.

In the right side of the skull, corresponding to the incision through the scalp, there is a round opening with smooth edges, the anterior portion of which is one centimetre posterior to the middle meningeal artery. The dura at this point has been opened. The calvarium smooth. No evidence of fracture. The dura is thickened and slightly adherent to calvarium. The thickening is more marked on the right side. On the inner surface of the dura, on the right side, there is a slight membranous formation, which can easily be stripped off, and in which numerous small hæmorrhages are seen and points of brownish

¹ A contribution to the forthcoming Medical and Surgical Report of the Boston City Hospital.

pigmentation. There are several foci of softening on the right side of the brain. These are more marked in the temporal region than elsewhere. The largest of these is in the first temporal convolution. It is three centimetres long, with irregular edges and quite superficial. The base is smooth and firm. The edges are yellow and sharply defined. At no place does the loss of substance extend more than three millimetres into the brain. There are similar but smaller losses of substance in the second and third temporal convolutions, and a very small one in the angular gyrus just above the fissure of Sylvius. There is also an area which is yellowish and slightly softened in the anterior central convolution opposite the second frontal involving a portion of the cortex one centimetre in diameter. The pia is of ordinary thickness, easily stripped off. The vessels at base of brain and throughout brain, perfectly normal. No pathological condition is made out within the brain itself. The base of skull shows no change. The ears and drum membranes perfectly intact.

The subcutaneous fat is slightly developed; muscles red. The peritoneum is smooth, and its entire posterior surface is elevated by an extensive hæmorrhage beneath it, giving to it a dark, almost black color.

Liver and spleen free from adhesions. Diaphragm on right side at lower margin of fourth rib; on left, at fifth intercostal space.

Both lungs are voluminous; the left free from adhesions. The pleura smooth. The entire posterior portion of left lung and the entire lower lobe are intensely congested and show numerous areas of hæmorrhage, which in part are small and circumscribed and in part form large irregular areas which are evidently due to confluence of the smaller. These areas are somewhat similar to areas of broncho-pneumonia, and are in connection with the bronchi. The blood-vessels of the lung are normal. In the bronchi there is a small amount of mucus mixed with blood. In addition to the areas of hæmorrhage, the entire lung is somewhat oedematous. The most congested portion of the lower lobe floats in water. The parietal pleura along the vertebræ is congested, and there is an infiltration of blood beneath it.

The right lung shows a few old and tolerably firm adhesions, which are most marked along the lateral surface of the lung. Almost the entire sub-pleural tissue of the wall of the thorax on this side is infiltrated with blood. This is most marked along the posterior surface, and extends from this around the apex of the thorax and down to the diaphragm, gradually becoming less in extent. There is no blood within the pleural cavity. The entire right lung is heavy and voluminous. The entire lower lobe, especially the posterior portion, is dark and hæmorrhagic. In one or two places the pleura is slightly elevated, apparently from hæmorrhage beneath it. Over the entire lung the pleura is perfectly smooth, with the exception of the places corresponding to the attachment of the old adhesions, and shows no rent or fissure. A section through the posterior surface of the lower lobe shows an extensive, irregular cavity filled with blood. The cavity is six centimetres long, and represents a long, irregular fissure of the lung, with lateral fissures radiating out from it. In several places it is immediately beneath the pleura, and the pleura in this place is separated from the lung by a mass of blood-clot which communicates with the cavity. The cavity contains

about fifty cubic centimetres of dark, clotted blood. The wall of the cavity, though irregular, is comparatively smooth. It does not represent a definite loss of substance in the lung; and on removing the coagulated blood contained within it, the walls of the cavity come into perfect apposition. The hæmorrhage here extends over the entire posterior part of the lower lobe. The lung is solid and sinks in water. Elsewhere there are smaller and more circumscribed hæmorrhages. The vessels of the lung are normal. No single, large vessel can be traced into the cavity. The cavity connects with the bronchi in several places. Elsewhere in the lung there is a slight amount of oedema.

Both layers of pericardium smooth. On the left ventricle, just at the juncture of the ventricle with the auricle, there is a large ecchymosis beneath the pericardium. The heart of ordinary size and weight. Firmly contracted. All of the valves of the heart normal. Coronary arteries normal. In the left side of the heart there is a firm mural thrombus two centimetres in diameter, which is attached to the auricle and the mitral valve at its ring of insertion. It is attached just above the middle of the aortic segment of the valve. On removal of the thrombus, it is found attached to a fissure in the endocardium of the auricle, which commences in the auricle just above the valve and extends downward into the valve. This fissure is one centimetre in length, and corresponds to the situation of the sub-pericardial hæmorrhage. The papillary muscle corresponding to this place also shows small fissures at the insertion of the cordæ tendinæ, with hæmorrhagic infiltration of the myocardium about them. These fissures are covered with a thrombus. The aorta is smooth.

The intestines are somewhat distended with gas, and are hyperæmic. The mucous membrane of the entire intestinal canal normal.

The entire posterior peritoneum is elevated by an extensive hæmorrhagic infiltration beneath it. This infiltration is more marked in the lower portion of the peritoneal cavity extending into the pelvis, and is more on the right than on the left side.

The spleen of normal size and consistency.

The liver large, rather pale and anæmic. The peritoneal surface smooth, the lobules visible. The gall-bladder contains rather thin, yellowish bile; the bile-ducts open.

Pancreas and adrenal glands normal.

The right kidney has an extensive hæmorrhagic infiltration around it. Its capsule is loose, and elevated by the hæmorrhage. There are numerous irregular fissures on both sides of the kidney; and in the middle there is a large fissure with an interval of one to two millimetres between the edges, which is filled with coagulated blood. Most of the fissures do not extend into the kidney for a distance of more than one to five millimetres, and none of them communicate with the pelvis. On section, there is a hæmorrhagic infiltration in the neighborhood of the fissures. Elsewhere the kidney is pale. About the left kidney there is also an extensive hæmorrhagic infiltration of the perirenal tissue. The surface of left kidney is smooth and free from adhesions. The capsule of the left kidney is slightly elevated above the surface. On section, the entire organ is distinctly congested, and blood can be pressed from the cut surface everywhere. The renal artery is occluded by a thrombus which ex-

tends up to the aorta. The renal vein is also thrombosed.

Both adrenal glands are imbedded in the hæmorrhagic infiltrated tissue. The pancreas shows no change. The urinary bladder and genitalia are normal.

The most careful examination showed no fracture of the walls of the thorax nor of the pelvis nor vertebrae. No fractured bone could be found in any portion of the body.

ANATOMICAL DIAGNOSIS.

Traumatic rupture of the right lung, heart and kidney. Pulmonary hæmorrhage from rupture. Thrombosis of heart. Sub-pleural, sub-peritoneal hæmorrhage from rupture. Embolus of left renal artery. Thrombosis of renal vein. Hæmorrhagic infarction of left kidney. Operation wound in scalp and skull. Old areas of softening in brain. Chronic pachymeningitis.

This case is in many respects an exceedingly interesting one. Although there are many cases reported of rupture of the lung and other internal organs without injury of external parts which would correspond with them, I have found no case in which the injuries of the viscera were so extensive. Most of the cases of rupture of the lung without injury of the thorax which have been reported have been due to direct violence applied to the wall of the thorax. The most frequent cases are those in which a wheel has passed over the thorax, or in which the thorax has received a violent blow. Cases have also been reported in military surgery of injury to the lung, sometimes followed by gangrene, from the effect produced by a spent cannon-ball striking the thorax. In all of these cases it has been assumed that the thorax was in a condition of extreme distention at the time of the injury, and the glottis firmly closed.

The man in this case fell from a height of less than twenty-five feet, bringing a lot of snow down with him. It could not be ascertained whether the contusion of the thorax was due to his having fallen on a projecting body. It is interesting to see that the rupture of the lung had been produced without any injury to the pleura over it. The hæmorrhagic infiltration extended over the rupture to the base of the lung, and from here on all sides, still beneath the pleura. There was no blood at all in the thoracic cavity. A close examination failed to show the rupture of any large vessel in the lung.

It is hardly possible to conceive that there should have been a rupture of one of the pulmonary vessels which had caused the destruction of the lung tissue. The case would have been more easily explained had there been numerous adhesions between the chest wall and the lung, but the adhesions in this case were almost entirely wanting. It is still more difficult to explain the rupture of the endocardium, and I have not been able to find the report of an analogous case in the entire literature. It is hardly possible to conceive of such a sudden increase of intra-thoracic pressure combined with intra-cardiac pressure which could produce such an injury. It would be more easily accounted for by a diminished intra-thoracic pressure combined with an increased intra-cardiac. There was an entire absence of any disease of the valve or of the endocardium which would have made the liability of

injury greater. The blood-vessels in the body everywhere were normal.

When we think of the anatomical structure and the situation of the organs in the thorax, it is difficult to understand how, in such an elastic tissue as the lung, an injury could take place as the effect of indirect violence. A consolidated lung is, of course, easily torn, because, owing to the inability of the lung to collapse, any violence applied to it only acts on a small portion of the tissue at a time. But here there was no evidence of there having been any previous consolidation. How the injury of the heart took place we have no means of knowing.

The rupture of the kidney is more easily understood, and cases are not uncommon of rupture of the kidney which have resulted from various forms of external injury. I know of one case in which a man fell from the roof of an omnibus, and, striking on the right shoulder, rupture of both liver and kidney took place. It is probable that the thrombus of the left renal vein was due to the injury of the tissues around the vein produced by the infiltrated blood. The embolus which plugged up the artery on the same side had evidently come from the thrombus in the left heart. That infarction of the kidney should have taken place after closure of both renal artery and vein is a direct confirmation of Litten's experiment. In Conheim's explanation of infarction after the closure of an artery, he assumes that the blood in the infarcted territory comes from a backward flow from the veins. Litten afterwards showed that the infarction took place when both vein and artery were tied, the blood entering into the tissue from the anastomosing vessels of the capsule and from the vessels along the course of the ureter. No infarction followed the ligation of the artery and vein when the capsule was stripped from the kidney and the ureter tied.

A REVIEW OF NINETY-TWO CASES OF DISEASES OF THE HEART OBSERVED IN THE OUT-PATIENT DEPARTMENT OF THE BOSTON CITY HOSPITAL.¹

BY HENRY JACKSON, M.D.,
Physician to Out-Patients.

MANY cases present themselves for diagnosis and treatment in an out-patient clinic with symptoms suggestive of some disturbance of the circulation, as dyspnoea, cough, œdema, or inability to work, in whom the diagnosis may be more or less difficult. Many of the difficulties may be removed if the physician directs his attention to a careful consideration of the size of the heart, to the relative proportion of the cavities and the muscular tissues of the heart, to its regularity of action and force, rather than to the presence or absence of endocardial murmurs. Again, many cases are found to have some disease of the heart, more often valvular, but occasionally of the substance of the heart which present no symptoms of such trouble, and in which a careful examination of the history may not elicit any symptom suggestive of cardiac trouble. As a matter of fact, a valvular lesion in itself gives rise to no untoward symptoms, causes no inconvenience to the individual, until as a result of the pathological change, of the incompetency of the affected valve, the heart be-

¹ A contribution to the forthcoming Medical and Surgical Report of the Boston City Hospital.

comes so dilated and the muscular tissues so weakened that it is no longer capable of supplying the system with properly oxygenated blood. During the stage of compensatory hypertrophy, as long as the defect in the valve is overcome by the increase in the muscular force, the disease is not suspected by the patient, and a diagnosis of the condition is made only by chance. Practically, from a therapeutic standpoint we do not treat the valvular lesion, but can help our patient only in so far as we are able to assist the heart to overcome the difficulties dependent upon the defect of the valve.

Clinically, disease of the heart may be divided into three essential classes: valvular, dilatation and hypertrophy, functional. Aside from the cases of dilatation or hypertrophy of the heart dependent upon valvular lesions, many cases are observed in which it is difficult and often impossible to determine the etiology during life. From some cause or other the muscular substance becomes weakened, and secondarily there follows a gradual enlargement of the cavities, with diminution in the thickness of the walls. The dilatation may be dependent upon fatty degeneration, fatty overgrowth (infiltration), some disease of the myocardium dependent upon obstruction of the coronary arteries, or may be met with as the result of prolonged overwork or alcoholic abuse. Again, the enlargement may be dependent upon arterio-sclerosis or renal disease.

The nomenclature of these various conditions is unsatisfactory; it cannot be based upon a probable pathological process, as in most cases this cannot be determined during life. In hospital records such cases are often entered as "Cardiac" or "Heart," etc.; and many death-certificates signed "Heart failure" might be more properly characterized as dilatation of the heart. It seems to me that the term "parietal disease of the heart," suggested by Dr. W. W. Gannett in a paper read before the Clinical Section of the Suffolk District Medical Society in March, 1893, is applicable to a large number of such cases. It expresses tersely and exactly the condition of the heart without committing one to an opinion as to the cause of the difficulty.

During two services of four months each, the one in the summer and the other in the spring, 92 cases were seen in which the heart was principally or only at fault as a cause of the symptoms complained of.

In 48 cases no valvular lesion was found as a factor in the production of the heart trouble; and these may, I think, be properly classified as "parietal disease of the heart." In these cases the diagnosis of some disease of the muscular substance of the heart was based upon a modification of the size of the heart, together with more or less disturbance in its action, as determined by enfeebled action, increase of rate, irregularity in rate or rhythm, or intermittency. Undoubtedly, in a certain proportion of these cases post-mortem examination would show some valvular disease. Further, in certain cases a first sound that I describe as short and valvular, would by some observers be considered as accompanied by a murmur; but in none of the cases was there a murmur defined in character, or localized with sufficient accuracy to warrant the diagnosis of a specific valvular lesion.

Five of the cases were classified as functional. In all the symptoms were palpitation and pain in the cardiac region; one, a man, said he "was afraid to work on account of his heart." In three, excess in tea, and in two, excess in tobacco, was assigned as the cause of the trouble. Two were young men of eighteen, and

three young women. In all these cases physical examination showed a rapidity of action, but no modification in the size of the heart or in the strength of the pulsations. The diagnosis of "functional disease" may here, as in so many other cases, be merely a mask to cover our ignorance as to some hitherto unexplained pathological change; but at the present time we can only assume some disturbance of the nerves regulating the action of the heart, as we have no evidence of any other pathological condition. In 39 cases there was some valvular defect.

The large proportion of cases of some heart trouble which present no evidence of valvular lesion shows us the importance of a careful consideration of the diseases of the parietes of the heart; a classification of the symptoms presented by such cases is interesting; and a uniform nomenclature, if obtainable, is certainly desirable.

FORTY-EIGHT CASES OF PARIETAL DISEASE OF THE HEART.

Thirty-six were men, ten were women, and two boys (aged respectively six and ten years). One of the boys had just recovered from diphtheria, and came in with a complaint of pain in the chest and palpitation. Examination showed an enlargement of the heart; the apex was outside the line of the nipple; the pulmonic second sound was accentuated; there was a slight soft systolic murmur, not transmitted, heard at the base. Here a diagnosis of fatty degeneration might be with propriety considered. The other boy, ten years of age, complained of loss of flesh, general debility and poor appetite; he had never been strong. Examination showed an enlargement of the heart; the apex was just within the line of the nipple, and the action was violent. Though no murmur was present, congenital deformity was suspected, though impossible of diagnosis. The age of the other cases was as follows:

9 cases, 30 to 40 years.
13 cases, 40 to 50 years.
7 cases, 50 to 60 years.
10 cases, 60 to 70 years.
5 cases, 70 to 80 years.

Where noted, the symptoms which caused the patients to apply for relief had existed for the following periods:

12 cases, 3 to 4 years.
9 cases, 1 to 2 years.
7 cases, several weeks.
9 cases, several months.
2 cases, 10 and 14 years respectively.

Seven cases were seen which presented no symptoms referable to the heart, but came in on account of some general disease; as one for herpes zoster, a second on account of a mastoid abscess, a third for some trouble with the eyes.

The symptoms complained of were as follows:

16 cases, pain in the chest, sometimes referred to the region of the heart, more often not localized.
22 cases, dyspnoea or shortness of breath.
7 cases, cough.
8 cases, palpitation.
4 cases, dizziness.
4 cases, general weakness.
2 cases, sudden attacks of faintness.
7 cases, cedema.

The most frequent and prominent symptoms were dyspnoea and distress, or sharply-defined pain in the chest, symptoms which in many instances have existed

for a long time, and often prevented the patients from doing their usual work. In none of the cases was oedema a marked feature, and in only a very few was albumen noted as present in the urine. In a few of the cases palpitation was given as the essential symptom which caused the patient to seek for advice.

Etiology.—In 23 cases no definite cause could be assigned for the condition of the heart. In 10 the confession was made of excess in alcohol, and it is probable that a good many more had used alcohol in large quantities, as patients are not inclined to make this admission to a house-officer. Seven patients had acute or chronic rheumatism. An examination of the age of the patients shows that all of them were in middle life, or past that period.

Physical Examination of the Heart.—In all the heart was enlarged, and the apex seen or heard, or both, outside of the line of the nipple. In one case the area of cardiac dullness extended two inches to the left of the line of the nipple. Irregularity of the action of the heart was noted in 13 cases, and irregularity with intermittency in 8 cases. In 7 cases rapidity alone was noted, while in 14 cases the only abnormal auscultatory sign was a marked feebleness of the pulsations, with a short valvular sound at the apex instead of the booming sound usually heard with the first sound at this place. I give a few typical cases:

CASE I. Man, fifty-three years of age. Complained of pain in the right chest. Dyspnoea for three or four years. Had been addicted to the abuse of alcohol. The heart was enlarged, irregular in force and rate, and the sounds were weak.

CASE II. Man, forty years of age. Complained of vertigo, slight dyspnoea on exertion, general malaise; was unable to work. Symptoms have existed for about a year. No cause could be assigned for his trouble. Heart was enlarged one-half inch to the left of the nipple line; the apex was seen and felt just beneath the nipple. Action of the heart occasionally irregular; first sound short, faint and valvular.

CASE III. Woman, forty years of age, a seamstress. She had noticed shortness of breath and palpitation for two years, which had interfered with work. No cause could be assigned for the trouble. There was slight enlargement of the heart; its action was very irregular in rate and rhythm. There was slight oedema of the legs; no albumen was found in the urine. It is possible that in this case there may have been a stenosis of the mitral valve, but the absence of any history of rheumatism or any abnormal sounds at the mitral valve renders the diagnosis at least doubtful.

THIRTY-NINE CASES OF VALVULAR LESIONS OF THE HEART.

Men, 26 cases; women, 10 cases; children, seven to ten years of age, 3 cases. The duration of the symptoms, when noted, was as follows:

- 5 cases, several weeks.
- 10 cases, several months.
- 4 cases, a year or more.
- 6 cases, 2 to 3 years.
- 5 cases, several years.
- 2 cases, 8 and 15 years respectively.

In 7 cases no symptoms were presented suggestive of any cardiac trouble. One case came in on account of gonorrhoea; another, who complained only of pain in the lumbar region, had a mitral regurgitation, with an enlarged heart in which hypertrophy was the essen-

tial factor in forming the increase of size. Fifteen years ago, when a boy, he had acute articular rheumatism.

In some of the cases the symptoms which brought the patients to the clinic had been noticed only for a few weeks; others who engaged in hard labor had suffered more or less for many years.

The symptoms complained of were these:

- 7 cases, a sense of pain or distress in the cardiac region.
- 15 cases, dyspnoea.
- 7 cases, cough.
- 4 cases, dizziness.
- 2 cases, oedema.

It is extremely interesting to note the ability to work as an index of the effect of the cardiac lesion on the individual. Only seven had given up their work on account of dyspnoea or shortness of breath; while, as stated, seven made no mention of symptoms suggestive of any cardiac disease. Only two of the men were engaged in light work, the others being day-laborers, or otherwise employed at hard, manual labor. Several of the patients who had marked valvular defects with great increase in the size of the heart were actively employed in hard labor. One case is especially noteworthy, that of a blacksmith, twenty-five years of age. He complained of dyspnoea on exertion, and a considerable swelling of the body and extremities which had existed for several months. He had acute articular rheumatism two years before he was seen at the out-patient department. Physical examination showed pallor and cyanosis; the heart was enlarged two inches to the left of the nipple; there was a loud double murmur at the base, a systolic murmur at the apex and in the tricuspid area. He came to the out-patient department for several months; and during all this time continued to support his family as a blacksmith.

Such an analysis of cases shows us very vividly that because a man has valvular heart-disease he is by no means to be considered incapable of working, and may live in comfort for many years, as in several instances the rheumatism which appeared to be the etiological factor of the disease had occurred many years before the patients were seen at the clinic.

Etiology.—In 14 cases no cause assigned; in 16 cases, acute articular rheumatism; in 7 cases, chronic rheumatism.

A boy of ten years was seen who had never had rheumatism or any acute infectious disease. He came in on account of epistaxis, but the mother said that he had never been "ragged." There was great enlargement of the heart, with violent action and a pre-systolic and systolic murmur.

The following forms of valvular lesion were seen:

- 16 cases, mitral regurgitation.
- 9 cases, mitral obstruction and regurgitation.
- 1 case, mitral obstruction.
- 5 cases, aortic obstruction and regurgitation.
- 4 cases, aortic and mitral regurgitation.
- 1 case, aortic and tricuspid regurgitation.
- 1 case, aortic regurgitation.
- 1 case, aortic stenosis and mitral regurgitation.
- 1 case, aortic stenosis.

THE Faculty of the Medico-Chirurgical College of Philadelphia has created three new clinical chairs, namely, genito-urinary surgery, orthopedic surgery and otology. These, together with the vacancy in the chair of clinical medicine, will be filled permanently at the end of the present session.

A BLOODLESS OPERATION FOR HÆMORRHOIDS.

BY THOMAS H. MAWLEY, M.D.,
Visiting Surgeon to Harlem Hospital, New York.

As hæmorrhoidal diseases of the rectum and anus are very common, and very often lead to very grave disturbances of the whole system, any line of treatment which will relieve or wholly subdue them, without any serious inconvenience or involving danger to life, will be welcomed by the profession.

At the beginning, it may be well to consider for a moment what we understand by the term "hæmorrhoids." From the etymology of the word we expect to find blood-tumors; but, in strict truth, in very many cases of so-called hæmorrhoids or piles the vascular system is totally devoid of any implication whatever; the small neoplastic formations which present themselves along the base, annular rim or roof of the anus and rectum, being histologically purely adenoid, papillomatous or vegetative. It is important that the anatomical distinction be made clear in this instance; for the treatment about to be commended applies especially, and almost solely, to those anal tumors which are, or were, entirely dependent on a diseased condition of the hæmorrhoidal veins, in other words, those which are of a venous origin only.

Another important question arises with respect to the relative frequency of these anal varices, designated piles. Are anal varices, dilatation of the veins or those tumor-like formations, either internal or external to the external sphincter, essentially a pathological condition? and, as such, in all cases, does it require active, radical measures for its abolition?

Very naturally, our course will be determined largely, in those cases, by a definite answer to this question.

If piles are all superfluous, neoplastic excrescences, then there can be no question as to our course in all cases.

During the past five years, I have made an examination of a very considerable number of supposed healthy recta on the living; and, in the dead-house, have carefully inspected under good light a large number on the cadaver. It was found that in both more than fifty per cent. had venous varices of the rectum. In many of the living, in whom varices of large calibre were numerous and extremely turgid, they never in their lives suffered from piles in any form, that they were aware of. Therefore, it seems to me that the hæmorrhoidal dilatation in man is rather a physiologically degenerative condition, which, in late life, is a source of no inconvenience, but which, at middle age, is often attended by or associated with such complications as to render it a distinct pathological lesion.

This view is further supported by the fact that cutting out, injecting or ligating off sundry hæmorrhoidal masses will not in all cases cure the disease. The varicose state of the upper rectal vessels remains, and nothing is wanted to promote their return but the exciting circumstances which caused their irritation in the beginning.

COMPLICATED HÆMORRHOIDS.

Diseased hæmorrhoids may be divided into three principal classes: (1) inflamed hæmorrhoids, (2) ulcerating hæmorrhoids, (3) bleeding hæmorrhoids.

Besides, we say internal or external, according as

they are without, or outside the external sphincter, or internal to it.

When internal medication has not succeeded, and, when palliative, topical applications have failed to afford permanent relief in chronic hæmorrhoids, in their radical treatment by the *bloodless* operation the majority may be cured, or at any rate greatly relieved.

THE ADVANTAGES OF THE BLOODLESS OVER OTHER SURGICAL MEASURES IN TREATMENT.

(1) The operation may be performed with a less number of assistants, and is very simple in its technique.

(2) As there is no division of the tissues, the dangers of infection, of abscess, ulceration and fistula are eliminated.

(3) There is no danger from the immediate loss of blood during operation or of serious secondary hæmorrhage.

In all cases, the evening before operation the patient should have the colon well cleared of all fecal matter by a brisk purgative.

In the morning, when everything is in readiness, the patient should be given from two to four ounces of whiskey, the quantity to be gauged according to previous habits, its effects, etc. After having cleansed, shaved and scrubbed the integuments over the ischio-rectal fossa, we are prepared for the first step in the operation, which is, effective *cocainization*, hypodermically applied. Local analgesia, when practicable, is much more preferable to pulmonary anesthetics. Our patient is more manageable, and there is no spurning of the feces over the operative field during manipulation.

Cocainization complete, the next and most vital step is complete and thorough *anal dilatation*. Without this being efficiently carried out, all else is a failure; but, to be painless and safe, it must be gradual and steady, or we shall rupture the muscle and leave our patient incontinent. In chronic, old cases, wherein, owing to malnutrition and interstitial changes in the sphincter, it has parted with its elasticity, laceration is very easy if we do not exercise caution.

Thorough anal dilatation accomplishes two purposes of great importance: First, it opens widely the anal portal, and so paralyzes the levator-ani that the lower fourth of the rectum—that part always implicated in hæmorrhoids—prolapses through the open vent, when it can be most minutely inspected and radically treated. This, however, is of minor importance compared with the profound effects which dilatation produces on the rectal disease. It is not material whether the hæmorrhoids belong to the inflamed, intensely itchy or irritable type; this stretching exercises a most salutary influence on them.

The third step, in simple hæmorrhoids, will be the separate treatment of each tumor by forcible pressure-massage. Before this is commenced, the entire cluster should be wiped clean and dry, and be then freely mopped with the cocaine solution. Now each hæmorrhoid is separately seized, close to its base, firmly between the tip of the thumb, index and middle fingers; first, put on a moderate but full stretch; then twisted; and finally so completely crushed that it is reduced to a pulp, and none of the investing tunics remain except the mucous membrane and its under stratum of fibrous tissue. When this has been completed the entire

mass is again pressed up inside the sphincter, a suppository of opium introduced, a pad and bandage applied, when the patient is returned to bed. An active but painless inflammation follows, and, as a rule, within two or three weeks absorption and atrophy have so reduced the vascular masses that nothing now remains but their shrunken, diminutive stems.

The ulcerative and hæmorrhagic varieties, along with cocainization and dilatation, must have superadded a special therapy appropriate to each.

Since January of this year, 1893, 32 cases of hæmorrhoidal disease have come under my care, in the hospital and outside. Many have come to me who feared anæsthetics, and others who were averse to having any cutting operation performed. In all, the permanent results have been eminently satisfactory; and from what previous experience I have had with this procedure, there is no reason to believe that the cures will not be as durable as those effected by other more sanguinary measures, which are not without danger in themselves, and are sometimes followed by the most lamentable consequences.

Of my latest series of cases, 17 were men and but 15 women. Fourteen were cases of simple, chronically inflamed hæmorrhoids, nine ulcerating and itchy, and nine bleeding. Four of the female cases were of the bleeding variety. Of the ulcerating type, in six of them there was a well-marked tubercular cachexia.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, Monday, November 6, 1893,
DR. CHARLES P. PUTNAM in the chair.

DR. J. B. MCCOLLOM read a paper entitled,

SOME REMARKS ON DIPHTHERIA.¹

DR. MASON: The interesting paper of Dr. McCollom deals with a subject which is practical and important to every one who is practising medicine. The bacteriological investigations seem to have left the matter in such a position that to-day no one is justified in making a diagnosis in a doubtful case of sore throat without cultures. The difficulty of an off-hand clinical diagnosis by inspection is obvious. In former years mistakes were very often made, and they are still made, as is evident from the number of cases that come to diphtheria wards, which, after a day or two, by the application of this method, are shown not to be diphtheria. In October, perhaps a dozen cases entered our ward at the City Hospital which turned out to be pharyngitis, tonsillitis or stomatitis, all sent to the hospital as diphtheria. The inspection of such cases always raises a doubt with regard to the diagnosis, which may not be determined for a day or two, and the question of isolation becomes important. In the hospital now building there will be facilities for isolating considerable numbers of doubtful cases, so that they will run no risk of contracting further disease. But fortunately, as Dr. McCollom remarked, these milder sore throats seldom become diphtheria. It is a rare thing for such a case to contract diphtheria, even

when in the presence of a considerable number of malignant cases. Such patients are sent away as soon as possible, either into another ward or away from the hospital. That, however, cannot be done until suitable cultures are made, a matter of a day or two. Occasionally, from some fault of the technique or some mistake or other, the bacilli of diphtheria are not found at the first examination, but are found subsequently. Therefore, it is best to have more than one culture made in cases in which the result is negative before sending such patients away from the hospital. This involves the stay of a few days, and by that time the patients are probably well enough to go out. From the clinical standpoint, the experiments at the City Hospital have been of great value, not only in separating these classes of non-diphtheritic sore throats from true diphtheria, but also in differentiating the mixed throats, the cases of scarlatina in which diphtheria exists from those in which no diphtheria exists.

With the disappearance of the visible membrane in the throat diphtheria does not end; that is, the bacilli may be found for a considerable length of time, and it is a question whether patients whose throats have cleared up and who present no discharge from the nose — nothing to indicate continuance of the disease — are to be regarded as well and sent home, or whether they should be retained for a longer time. The Klebs-Löffler bacillus may be found for an indefinite time in the secretions of the nose and pharynx. The longest period that I have observed is three weeks after the membrane had disappeared. The child was apparently well, the symptoms had gone, the appetite was good, the patient was becoming ruddy, and yet the specific bacillus persisted for three weeks. With our present knowledge, it does not seem proper to send patients in that condition away from the hospital or into another ward; therefore they are retained until the Klebs-Löffler bacillus is absent from the secretions of the nose and of the pharynx. I believe that this organism may persist for a much longer time than three weeks. Perhaps Dr. Williams has more knowledge on that subject than I have, but I think I have read of a case in which some fifty days elapsed before these organisms entirely disappeared. Fortunately, these cases are few, and we do not have to crowd our wards with patients requiring such a length of time for convalescence. It may be doubted whether these late bacilli are not of the modified form, to which Dr. McCollom referred, which are not active conveyers of the poison. Although every one is now upon the alert in the examination of throats, it does not seem probable that in the near future differentiation with this great degree of care will be the general practice. In the lower parts of the city I suppose that bacteriological cultures are not practicable, unless, indeed, this very excellent scheme which Dr. Ernst wishes to inaugurate can be carried out by the majority of physicians practising all over the city.

DR. WILLIAMS: I am sure we have all been very much interested in Dr. McCollom's paper, and it is certainly very important that this question should be spoken of repeatedly. Very much has been said and done about cholera, and comparatively little said about diphtheria, a disease which is always with us and very fatal in its character. A good deal is now being done but there is more still to do. It seems as if the disease were transmitted from patient to patient directly in the majority of cases. Many of the cases which come to

¹ See page 107 of the Journal.

the City Hospital give a history of having been in the same house with diphtheria or having had a brother or a sister ill with the disease recently. Sometimes, of course, we do not get a history of exposure; but it is rather significant that we do in so many cases get a history of direct exposure. The question of bacteriological examinations interests me very much. I believe I was the first to use that method of diagnosis in this community, and its importance will soon be generally recognized. As regards the mild cases of which Dr. McCollom speaks, they are especially dangerous to their neighbors, because their true character is often not realized and therefore proper precautions are not taken. It is not unusual to find mild cases that to the unaided eye do not present the ordinary symptoms or appearances of diphtheria (in fact the throat may look normal), but that are shown by bacteriological examination to be diphtheria.

I recall one case which two physicians saw, and said there was nothing in the throat. It seemed to me there was a slightly suspicious spot; I did not call it membrane. There was not much redness; it was nothing like as angry a throat as you get in mild tonsillitis, but cultures showed the presence of the bacilli, and the case proved to be one of diphtheria. I think it is very important that examinations should be made where there is the slightest symptom connected with the throat among those who have been about a patient with diphtheria. It is not necessary to wait until you get symptoms of severe tonsillitis, or follicular tonsillitis, or something very distressing; but it is well to be on one's guard, for sometimes you find bacilli when you least expect to—at least, that has been my experience several times.

As regards the detection of these bacilli, I think in some cases, especially early in the disease, when you have chiefly the bacilli of diphtheria, and these are not obscured by other organisms which develop later, they may frequently be detected without cultures. In such cases it is very easy to take a cotton swab, and, after brushing it over the throat, rub it on a cover-glass, dry, and stain with Löffler's blue solution and examine under the microscope. In many cases one can find the bacilli in a few minutes. When you find them, this method of examination is of importance; when you do not, it has comparatively little weight; that is, you cannot exclude diphtheria by means of this preliminary examination. Of course, one should not rely upon this alone; cultures should be made as well.

As regards the method of carrying the bacilli. This contrivance which I have in my hand is very simple. Here is a small stick with a bit of cotton around the end. The cotton end is brushed over the suspicious places in the throat, and the stick is then placed in a strong test-tube, which is stopped with sterilized cotton. To prevent the specimen from drying, a small piece of cotton moistened with water may be placed above the stopper, and the tube may then be closed with a cork to prevent evaporation. This contrivance, which has, of course, been previously sterilized, answers very well to carry the swab to the laboratory where cultures can be made.

As regards the length of time during which the bacilli may persist in the throat, I have in mind several cases, some of which I have already reported. In one case they persisted about six weeks, in another about two months, and in another nearly three months. The last case is interesting because the patient left the

hospital and some weeks later had hoarseness; and on examining the throat a membrane was seen in the larynx, and the bacilli were readily found, so that in some cases the bacilli may exist in the throat a long time. Isolation should not be terminated, although the throat may look perfectly normal, until the bacteriological examination fails to show the dangerous bacilli. This may sometimes be weeks after the throat has been clear of membrane.

Not infrequently you find diphtheria coincident with other diseases. This is especially the case with scarlet fever. In measles you sometimes find diphtheritic membrane, and it is well to remember that in typhoid fever you may in some cases also find membrane in the throat in which the diphtheria bacilli are present. Patients, of course, may get diphtheria or scarlet fever if placed near those ill with either of these diseases. Diphtheria does sometimes occur in patients who have had tonsillitis or some membranous affection of the throat, and who have been exposed to diphtheria. I have seen some cases of this kind. I think the tradition that cases of tonsillitis do not acquire diphtheria has exceptions; it simply means that that has not been observed; and I think, with the more modern means at command, we shall be enabled to detect more cases of this sort.

DR. SPRAGUE, of Providence: I have been very much interested in the paper of this evening, and certainly the subject is one in which we are all interested. My studies at the present time are more in the line of diseases of the ear and throat, and I do not see many cases of diphtheria; but I meet cases in which at the time it is impossible to make the diagnosis. In Providence our board of health has been in the habit of making the diagnosis of diphtheria by the death-certificate and of scarlet fever by desquamation; but within a few months or a year, they have been going into the bacteriological examination, systematizing things, making the work more thorough. I think that the ground has been very ably covered by the reader and by the discussion, and that little remains to be said.

DR. F. C. SHATTUCK: Like everybody else, I suppose, I hailed with great joy the announcement of a method which would enable us to distinguish diphtheria from other throat affections, because I have always felt it to be one of the most difficult diagnoses in medicine, to determine in certain cases whether diphtheria existed or not. Of late years I have not seen many cases of diphtheria. When I had a dispensary district I saw an immense deal of it. Last winter I saw a child with a suspicious throat. I had Dr. Stone make cultures; the Klebs-Löffler bacillus was found and the case was treated accordingly. A few weeks later another child in the same family came down with a throat which clinically, macroscopically, was certainly diphtheria. There was false membrane on the tonsils and spreading up on the soft palate. At my request Dr. Stone made cultures of this case. His first result was negative. He made a second examination which was also negative. I treated the case, however, exactly as if it were one of diphtheria, and I must say that I should not feel safe in following any other course at present. I do not feel sure that this method has been practised long enough, or that we know enough about it to warrant us in treating throats which look like diphtheria to the naked eye in any other way than as if they were diphtheria. When a new method of

diagnosis is announced, just as when a new drug is brought forward, I think the tendency of the profession is to be too enthusiastic at first. Perhaps I show my ignorance in speaking as I do; but I should not feel satisfied in my own family or in any family to remove restrictions and to allow a patient to go about who had a throat which clinically was diphtheria, although the bacteriological examination was negative. I shall be very much interested to see what ultimately comes out of this. If we have a sure means of differentiation it will be an immense boon. But a new terror is added to life in the fact that patients sometimes for fifty days after naked-eye manifestations have vanished, have the bacilli in their mouths and noses or throats, and consequently may transmit the disease to others. In the nose there are so many hiding places for bacilli that I cannot see how a simple little swabbing, with negative culture results, can make us sure of their absence.

DR. MASON: With regard to Dr. Shattuck's remarks it has struck me too that some cases do not present the Klebe-Löffler bacillus when they should do so according to the appearances, and that has seemed to me to be due rather to faulty technique or to some mistake than to the fact that these bacilli might not be found perhaps by more prolonged search. Such a case came under my observation not long ago in which a patient had membrane in the throat — not very much, but there was laryngeal stenosis and tracheotomy was required. It was evidently a case of tracheal diphtheria, but the bacilli were not found at the first examination. So I think that such negative results are only of value from that point of view; they are negative, but they do not prove that the subjects do not have diphtheria.

DR. SHATTUCK: I do not see how greater care could have been taken in this case. A thoroughly competent man was selected who was perfectly familiar with the appearances of the bacilli and their manner of growth, and at my solicitation he made two examinations with the greatest care, the results of both of which were negative.

DR. WILLIAMS: I think what Dr. Shattuck said is very suggestive. It is a point which has been in my mind, and in fact in a paper which I read last June before the Massachusetts Medical Society, I said that the cultures were not infallible. I do not think they are to be absolutely and entirely relied upon. I think it is possible to have some slip so that you do not get a growth of the bacilli, but our ability now to detect diphtheria early is very much greater than it used to be, and this method is certainly a great step in advance, and will render much service. I had a case within a few days where examinations were made with great care with negative results. The patient died, and no bacilli were found in any of the parts about the throat, tonsils or anywhere, except in the little chink between the vocal cords. The trachea was taken out and cut open with carefully sterilized scissors, and a small drop of purulent matter about the size of a pin's head was found; cultures were made, and the bacilli developed. I recall a case in which a child had measles, and coughed up large pieces of membrane. It seemed to me to be a case of diphtheria; and I held to that diagnosis, which was based on a preliminary examination, in which the bacilli were found, although I was told that the bacilli were not found in the cultures. Another specimen was obtained and another culture made, and no bacilli found: then an-

other specimen was taken from the throat and examined directly in the way I have referred to for making the preliminary examination, and the bacilli were perfectly evident. The cases that Dr. Councilman and I studied together last year included some which came from two institutions of the city where there are a considerable number of children; and in these institutions there happened to be during a period of about six weeks cases of diphtheria alone, cases of membranous throats without the bacilli, cases of scarlet fever alone, and cases of scarlet fever with diphtheria. Similar conditions must, I think, favor the development of these two diseases. Let me repeat: it is well to bear in mind the possibility of failure to find the bacilli by the method of culture. Corrosive sublimate which is often used as a local application inhibits the growth of the bacilli; one part in thousands will inhibit the growth of the bacilli, prevent their growing at all on the culture media; but a pretty large proportion of the corrosive sublimate is not sufficient to kill the bacilli. While speaking of corrosive sublimate I should like to say that it does not seem to me a very serviceable agent as a local application; it is very irritating even in a dilute solution if used persistently. When applied in the strength of 1 to 2,000 or even 1 to 500 it does not seem to have much effect in stopping the growth of the bacilli and the spread of the membrane. I have tried treating one part of the throat with corrosive sublimate in pretty strong solution, and not treating other portions; and the parts treated with corrosive sublimate did not do as well as the parts not treated. I am very sure that corrosive sublimate as a local application may do harm locally as well as cause poisoning; but I understand from the Secretary of the Society that the question of treatment is not so much before the meeting as that of diagnosis, so I will not enlarge upon the treatment of diphtheria.

THE NEW YORK NEUROLOGICAL SOCIETY.

STATED Meetings, held at the New York Academy of Medicine, Tuesday evenings, December 5, 1893, and January 2, 1894, DR. M. ALLEN STARR, President, in the chair.

GLIO-SARCOMA OF THE BASAL GANGLIA.

DR. FREDERICK PETERSON presented a specimen of gliosarcoma of the basal ganglion. The case was that of a man aged fifty years, who had been in excellent health, with the exception of occasional attacks of vertigo and slight headache, until June 8, 1893, when he fell to the floor in his office. He had a general convulsion, and was unconscious ten hours. In two weeks he was well enough to return to his office from his home in New Jersey, and to continue at work for five days, when headache and malaise kept him at home. Four weeks after his first convulsion he had five or six more of short duration, and rather left-sided in character. At this time he presented the following symptoms: left hemiparesis and hemianesthesia, left hemianopsia, tendency to somnolence, pupils equal and small, sometimes delirious, great frontal headache, pulse 52 to 60 per minute, respirations slow, slight optic neuritis. The diagnosis of sarcoma or glioma situated deep in the brain, so as to affect the posterior limb of the right internal capsule, was made. An operation was out of the question. The man was un-

conscious during the last three days of life. At the autopsy, made just five months after the first apparent onset of symptoms, a glio-sarcoma was found, about two inches in diameter, occupying the region of the basal ganglion, especially posteriorly, and projecting upwards into the right lateral ventricle and downwards somewhat into the right crus. It was not strictly demarcated, and there was some infiltration into the white matter of the brain, with here and there some areas of softened brain tissue. A secondary tumor, the size of an almond, was found attached to the dura mater on the right side, compressing the cortex in the region of the angular gyrus.

DR. ALFRED WIENER described a case of

SUBACUTE UNILATERAL BULBAR PALSY, WITH AUTOPSY.

The patient was a young man aged seventeen years. Family history negative with respect to any hereditary nervous trouble. Patient had always been in good health up to two years ago, when he was taken down with an attack of perityphlitis, from which he recovered after five weeks of illness. About two years ago last spring the glands on both sides of his neck in the region of the sterno-cleido-mastoid muscles began to enlarge. In the summer of the following year, 1892, an abscess formed in one of these glands and had to be opened. In August, 1892, the glands on the right side, together with a large portion of the sterno-cleido-mastoid muscle, were excised. Those on the left side were removed the following month, and were found to be of tubercular nature. The patient rapidly recovered, and nothing was noticed in the way of any disturbance of the parts which might have been involved in the operation. In November, 1891, it was discovered that the patient's tongue deviated to the right side, and shortly after this he experienced some difficulty in swallowing. He soon became hoarse, and coughed with difficulty, and within a space of ten days the patient developed a complete unilateral palsy of the right side of his tongue, soft palate, pharynx and right recurrent laryngeal nerve. There was no disturbance of his respiratory or cardiac organs, or other condition present which should have called attention to an affection of any other cranial or spinal nerves excepting the ninth, tenth, eleventh and twelfth. The symptoms remained stationary for a time; then the patient began to grow very much weaker; and suddenly, on March 26, 1893, he had an attack of respiratory failure. From this he partially recovered, and then continued in a condition of slight respiratory difficulty. He could hardly speak above a whisper. He had excessive salivation. On April 11th he could barely protrude his tongue beyond the edge of his teeth. His lips remained normal, and could be brought into perfect apposition. The palate and pharynx on the left side remained normal. On April 20th he had another attack of respiratory failure, which proved fatal.

The autopsy, made six hours after death, revealed that the motor cortex, internal capsule, crura cerebri and pons were normal. The nucleus of the twelfth nerve on the right side was much diseased, while on the left side it was diseased to a slight degree. The nuclei of the ninth, tenth and eleventh nerves were slightly affected, a little more on the right side than on the left. The respiratory bundle appeared to be completely degenerated on the right side, while on the left, in the region of the hypoglossal nucleus, its lower

and anterior portions were diseased. In the region of the ninth nerve a few fibres were affected. The intramedullary roots of the ninth vagus, vago-accessorium and hypoglossal nerves were less prominent on the right side than on the left. Otherwise, everything appeared to be perfectly normal up to the exit of the first cervical nerve in the spinal cord. As regards the nature of the lesion, no tubercle were found, as had been expected, nor were tubercle bacilli found on microscopical examination. There was simply an atrophy of the ganglion cells and fibres motor in function.

From a careful consideration of the preceding case and autopsy, Dr. Wiener drew the following conclusions:

(1) That the region of the hypoglossal nucleus gives origin to nerve-fibres which supply the tongue, palate, pharynx and larynx on one side of the body.

(2) The column of nerve-fibres known as the respiratory bundle consists of fibres from the glossopharyngeal, vagus and vago-accessorium nerves; and the lower and anterior portion of this column probably serves as the locality for the vagus and vago-accessorium fibres.

(3) That the glossopharyngeal nerve seems to control the reflexes of nausea and gagging in the soft palate and pharynx, and also to send some of the motor filaments to the pharyngeal muscles. These latter filaments take their origin in the hypoglossal nucleus, and ascend in the respiratory column to the nucleus proper, and then make their exit with the glossopharyngeal nerve.

(4) That the soft palate muscles are not innervated by fibres from the seventh nerve.

THE PONS-MEDULLA FLOCCULUS TRIANGLE AS A TUMOR SITE, WITH PATHOLOGICAL FINDINGS.

DR. ROBERT SAFFORD NEWTON read a paper on this subject, which he illustrated by the following case:

Female, aged twenty-eight years. She entered St. Mary's Hospital July 10, 1893, complaining of a constant headache for a fortnight, with morning vomiting and sickness for seven days. No history of any trauma; no specific history; family history negative. Two days after admission she was examined, and apart from a silly manner and a slight drawing in her speech, she presented no symptoms. On July 20th the patient became weak and fell to the floor. She muttered to herself during the night, and moaned about her head. The pain appeared to be diffuse. She was dull and stupid. Her speech was prolonged and tedious. At this time there was no defect of the cranial nerves. Pulse 45 per minute. She had a shuffling walk, with some tendency to go to the right. The superficial reflexes were present; the knee-jerk was increased on the right side. On July 22d the patient became quite deaf. The headache was very violent, keeping her awake. July 24th, patient very feeble; deafness marked, especially in the left ear; no tenderness nor discharge. The patient stated that she could not see well, but the ophthalmoscope showed no marked lesions. Upon standing up, she was projected to the right very forcibly. The movement at each trial was accompanied by a look of fear, paling of the face, dilatation of the pupils and bathing of the surface in cold perspiration.

From this time on the patient failed rapidly. The

sight became worse; the patient grew petulant and childish; her appetite remained fairly good. Nystagmus was present for one day only. The external rectus was also temporarily affected. She had a transient facial tic. The sense of smell was present to the last. Optic neuritis first appeared in the right eye, then in the left, and rapidly went on into total blindness. She also became totally deaf. Her taste sense was not appreciably affected, although she occasionally complained of a hot, scalding feeling in the back of the tongue and palate. Her pulse was slow from the beginning; towards the last it dropped as low as 10, 12 and 14 beats per minute, and three days before her death it dropped to 6 beats per minute. There was no anæsthesia nor implication of the pain, temperature, tactile or muscular senses. She never had any convulsive seizures or paralytic attacks. The weakness steadily progressed; there was loss of control of the sphincters; the respirations became slow, and gradually ceased. Just before her death she was still able to distinguish between whiskey and milk.

The autopsy was made ten hours after death. Upon removing the brain, an enormous tumor with a central projection was found on the left side. The swelling was somewhat triangular; its apex was under the thalamus and geniculate body, its base crowding the cerebellum off from the medulla, and its side line not quite reaching the middle of the pons. In the central pons region was a projecting mass, shaped like a thumb. The bulk of the growth was a cyst. The left half of the pons was much softened, and the medulla and cerebellum were flattened. The olfactory nerve was intact. The optic nerve was swollen on the left side. The third and fourth nerves were intact. The fifth and sixth also seemed to have remained unchanged. The seventh nerve was on one side of the growth, the eighth on the other. The nuclei of the ninth, tenth and eleventh nerves were pushed aside by the change in position of the floor of the medulla. The nucleus of the twelfth nerve was entangled in the growth. The cyst began at the margin of the fourth ventricle by a blocking of the channel of communication between the lateral cisternæ of the ventricle and the cavity of the arachnoid.

SYRINGO-MYELIA: CENTRAL GLIOMA OF THE SPINAL CORD, WITH SPONTANEOUS CENTRAL HÆMORRHAGE.

DR. CHARLES L. DANA read a paper on this subject, and narrated the history of the following case:

The patient was a man who had a central gliomatous tumor in the lower part of the dorsal region of the spinal cord. This tumor progressed slowly for two or three years, causing, during that time, the symptoms of a transverse myelitis chiefly, although the presence of a spinal tumor was suspected. Among other symptoms there was anæsthesia of the right leg extending up to the twelfth dorsal spine, and involving touch, temperature and pain sensations. Anæsthesia involved to a lesser extent the left leg. Just before the man's death a large hæmorrhage occurred, which was confined to the centre of the spinal cord and which caused exquisite pain; the man, in fact, dying from exhaustion. Upon post-mortem examination a large central hæmorrhage, destroying nearly every particle of the spinal cord at the level of the seventh dorsal segment was found. This hæmorrhage extended up and down for a distance of about three inches. Around the hæmor-

rhage and above it were evidences of a gliomatous infiltration involving nearly the whole of the transverse area of the cord at that level. Very striking secondary degenerations, ascending and descending, were found. The case was one of glioma of the spinal cord, without there being any cavity formed. Although clinically, and in one sense, pathologically, it would be a case of syringo-myelia, yet that name cannot strictly be applied to it.

In commenting on this case, Dr. Dana referred to the question of the existence or the non-existence of a pain tract, and the advisability of our searching for it. The psychologists seem to have come to the conclusion that pain is not a sensation, but a form of feeling; that it is not to be classed with the sensations of touch or temperature or heat; that it does not have peripheral end organs and that there are no nerves in existence which on irritation alone produce pain; that there is no such thing as a pain tract; that in attempting to locate such a tract we are pursuing a will-o'-wisp. Dr. Dana said that after a very careful study of this question he has been converted to the psychologist's view. If we claim that there is a special tract for pain, we can just as well claim that there is one for hunger and various other sensations. If there is a special tract for any of the common subjective sensations, there must be a special tract for all.

DR. B. SACHS said that in former days he held to the view that pain was nothing more than an intensification of the ordinary tactile sense; and in the majority of cases we meet with such an explanation would hold good, and under such conditions we would not look for any special pain tracts. The clinical facts that have been brought out with regard to syringo-myelia, however, do not bear out that theory. Touch and temperature sense may remain normal, whereas the pain sense is entirely lost. The psychologists' view of this question is one that is rather difficult to reconcile with the clinical facts we have obtained from syringo-myelia. On the other hand, this disease is very destructive and irregular in its course, and for this reason is rather an unsafe guide for us to go by in trying to determine physiological functions.

DR. C. A. HERTER said that several years ago he hemisected the spinal cord of a monkey in the mid-dorsal region; he was unable to find in that case any evidence of a loss of sensibility to pain either on the same side as the lesion or on the opposite side. He also performed this experiment on an opossum, with a like result. Mott, in his experiments, cut the antero-lateral ascending tract and was unable to find any evidence of loss of sensibility to pain. The results of experiments on animals, of course, cannot be applied directly to man. The subject brought up by Dr. Dana is an interesting one, and up to the present time we have not enough cases on hand to base any definite conclusions upon.

DR. LANDON CARTER GRAY said that in our present state of knowledge as regards the exact functions of the various columns of the cord—the columns of Burdach and Goll and the so-called column of Gowers—and the uncertainty that exists as to the exact demarcation of the latter, we can arrive at no definite conclusions as to the location of the pain tracts. So far as clinical evidence goes, there certainly is such a thing as a pain sense. In hysteria the tactile sense may be preserved, while the pain sense is entirely lost.

DR. STARR said we must admit the existence of pain sensations and of a centripetal pain tract. That tract must necessarily go in through the posterior nerve roots, because we have painful sensations of a hallucinatory character in locomotor ataxia. It must extend for a distance in the central gray matter of the cord. We have now on record over seventy cases of syringo-myelia, with autopsies. In these cases there is a decided loss of pain in a certain limb. If the affected limb is an arm, then the cavity in the cord is in the cervical region, and the pain sense is preserved in the body and legs. Therefore these sensations, though they may pass for a little distance in the central gray matter of the cord, afterward pass into the white columns. The central gray matter contains numerous cells, each of which sends its fibres into the antero-lateral columns and these pass upwards. While it is by no means positive that the antero-lateral columns transmit sensations of pain, all the facts seem to point to the correctness of that theory. The column of Lissauer, to which one of the speakers referred, can have nothing to do with the transmission of pain sensations. It consists only of short fibres, does not increase in size from below upward and cannot transmit impulses upwards for any great distance. The sense of hunger is by no means analogous to the sense of pain, as Dr. Dana intimated. We must distinguish between a common sensation and a special sensation.

In conclusion, Dr. Starr referred to a case reported by Edinger, with autopsy, in which the lesion was found in the parietal region on one side, and in which the symptoms were chiefly those of intense pain radiating in the opposite side of the body. Edinger described it as a case of central lesion, with sense of pain.

DR. DANA then closed the discussion. He said that his views regarding the non-existence of a pain tract were only arrived at after a long and thorough study of the subject. When we come to mix up pain sense and touch sense and heat sense, etc., we are showing a mental confusion that is unworthy of advanced neurologists. Pain and touch are entirely different. Pain is a subjective or common sensation. Touch is objective. Pain is much more closely allied to hunger than it is to touch. Pain is not a special sensation, but a modification of it. We may have a painful pricked wound, etc., but we do not have a simple sensation of pain. It is always combined with something else. If we can get rid of the idea that we must keep on hunting for a pain tract, it will save much exertion and many futile experiments on monkeys and men.

A CASE OF INFANTILE, CEREBRAL, SPASTIC DIPLEGIA.

DR. F. PETERSON presented the fresh brain in this case. The patient was a female infant, aged twenty months, with congenital diplegia; that is, spastic paralysis of all four extremities. The child was subject to convulsions, had enormously exaggerated kneejerks and ankle-clonus. Its head was exceedingly small. At the autopsy, the skull-bones were found to be considerably thickened, and all the sutures and fontanelles closed and united. The dura was very thick. There was no increased amount of sub-dural fluid. Over each hemisphere, a large group of convolutions, including especially the motor area, were found wanting. The vacuum caused by this atrophy was filled partly by sub-dural fluid and partly by the bulging of each ventricle. There was no internal hydro-

cephalus. There was no communication between the ventricles and the exterior of the hemispheres. A microscopical examination of the spinal cord showed degeneration and atrophy in the lateral columns.

DEAFNESS DUE TO A FOOT-BALL INJURY.

DR. J. LEONARD CORNING narrated the history of the following case: The patient was a young man aged eighteen years, who received a severe kick directly over the right ear while engaged in a game of football. He was first seen by Dr. David Webster, who, upon careful examination, found that there was total deafness on the right side; aerial and bone conduction were suspended. There was no trouble of the middle ear, and the drum was in perfect condition. There was slight bleeding of the external ear. There was no evidence of fracture. The case was then referred to Dr. Corning, who applied to the ear a rapidly interrupting faradic current, which was allowed to pass through the ear about ten minutes, when the hearing was so far restored that the patient could hear the watch at a distance of six inches. Before making the application, the external meatus was plugged with absorbent cotton moistened in salt solution. A severe tinnitus which existed with the deafness was also relieved. Dr. Corning said he had no idea what the lesion was, or why improvement followed the use of the current; it was employed simply as an empirical measure. The young man's hearing is now entirely restored. There was no suspicion of hysteria. The visual field was not tested.

DR. DAVID WEBSTER said he supposed the deafness was due to concussion either of the auditory nerve or of the labyrinth, of which he has seen cases reported. Temporary blindness has been produced by a sudden blow on the brow, without ophthalmoscopic or other lesion. Most of those cases, however, are due to fracture of the base of the skull, involving the optic foramen and producing nerve atrophy. He has never seen another case similar to the one narrated by Dr. Corning.

DR. STARR suggested that the case might have been one of traumatic hysteria or concussion of the auditory nerve. In consultation with Dr. Jacoby he recently saw a case of total deafness in both ears, of central origin, in which a temporary improvement in the hearing was produced by the use of a strong galvanic current, about six milliamperes, which is a strong current for the acoustic nerve.

DR. RALPH L. PARSONS reported

A CASE OF ACROMEGALY.

The patient was a man aged thirty-six years. Family history negative. Never had venereal disease nor used alcoholic stimulants. He was in good health until eighteen years ago, when he had an attack of malarial fever. From this he recovered, and has had no recurrence since. Ten years ago he was told that he stooped and carried his head to one side. Eight years ago he began to suffer from a pain in the back of his head. This came on mostly at night, and not oftener than once a week. Subsequently the headaches occurred more by day than at night. Latterly they have increased in frequency and duration, and have often been excruciating in character. The pain was usually most severe at the occiput, but would also involve the left parietal and frontal regions; the right side of the head was unaffected. About six years ago his attention

was first called to the large size of his hands. He then for the first time perceived that they were of extraordinary size. He does not know for how long a time this increase in size has been taking place. He cannot say whether they have increased in size during the past six years.

A careful examination of the patient was made in October last, with the following result: Weight, 227 pounds. No pronounced symptoms of organic disease. Hair rather coarse, but natural in condition; left ear slightly thickened; forehead retreating; superciliary ridges quite prominent; no exophthalmos; malar bones rather prominent; cheeks appear rather sunken; nose broad and full at the nostrils; lips normal; tongue decidedly enlarged, obstructing free articulation; alveolar processes normal; teeth not separated; chin elongated; head inclined strongly and habitually to the left side and forwards. The hands were large and spade-like, the right hand being decidedly the larger. The soft tissues of the hands and fingers were firm and resilient, as though infiltrated by an elastic substance; they did not pit on pressure. Wrists rather large; arms normal. Thorax and pelvis normal. The feet were large, but perhaps not more so than in the case of many men of his weight. The patient has perspired very freely for the past ten years; of late the perspiration has been decidedly offensive. Besides the headaches already referred to, the patient also complained of pain in the left ear and eye, the latter coming on after reading or using the eye in a strong light. He does not think his eyesight has become impaired. Appetite and thirst excessive. No marked mental symptoms.

On the 21st of October last, by advice of Dr. Starr, the patient began the use of thyroid extract, five drops three times daily. The dose was gradually increased until he received fifteen drops three times daily. With the exception of tonic baths, general hygienic measures and a regulation of the diet, no other treatment was given. At the present time the patient reports that he is feeling decidedly better. He is more cheerful, and his headaches have been relieved to a very great extent. They have not, however, entirely disappeared. There seems to be no change in the dimensions of the hands. His weight has increased rather than diminished. There has been a great improvement in the subjective symptoms, but there is still a reasonable doubt whether this improvement is due to the direct action of the medicine or to the patient's mental status, induced by the fact that something is being done for his relief.

DR. CORNING was inclined to think that the improvement in the condition of the patient was due to the medication employed, rather than to the mere fact that something was being done for him. Such patients, he thought, are usually not of a very imaginative turn of mind.

DR. STARR said he was somewhat responsible for the use of the thyroid extract in the case narrated by Dr. Parsons. There was nothing original in the suggestion, as this method of treatment has been pursued in England in a number of cases of acromegaly. It is purely empirical. The supposed lesion of acromegaly is an increase in the size of the pituitary body. It is questionable whether it is in any way related to the thyroid gland. The eye symptoms in Dr. Parsons's case interested him, because in two other cases of acromegaly coming under his observation there was a

concentric diminution of the visual field, and in one hemianopsia; the latter symptom is quite common, and is probably due to pressure on the chiasm by the enlarged pituitary body. In one case of acromegaly seen at St. Luke's Hospital last spring the patient died of pneumonia, and at the autopsy the pituitary body was found to be normal. There was nothing to account for the peculiar growth of the bones.

DR. PARSONS, in reply to Dr. Webster, said it is generally supposed that there is a sort of relationship between acromegaly and myxedema; whether this belief is well founded, or what that relationship is, he does not know. While his patient was not of an imaginative turn of mind, still he was hopeful; and that element would influence his mental state and perhaps even improve his physical condition.

ERGOT IN THE TREATMENT OF PERIODIC NEURALGIAS.

DR. WILLIAM H. THOMSON read a paper on this subject, in which he gave the histories of a number of cases of severe periodic neuralgias in which the symptoms were promptly relieved by the use of ergot in large doses. In all of these cases the disease was of long standing, and the usual remedies had been employed without avail. Dr. Thomson said his method of administering the ergot in migraine was as follows: The fluid extract of the drug is employed, combined with an equal quantity of elixir of cinchona, to obviate its tendency to cause nausea. Two drachms of this mixture is to be taken in water as soon as the premonitory symptoms of the headache are noticed, and the patient is advised to lie down and keep very quiet. If, after an hour, the headache continues, a second similar dose is taken, and then a third in another hour if necessary. As nausea is such a general accompaniment of this affection, it is provided that if either of the doses be vomited, it should then be taken in an enema of two ounces of water. This medication, the speaker said, rarely fails to arrest the attacks, even in long-standing cases, and with a preventative course of intestinal antiseptics in the intervals, the relief from the malady has often proved permanent.

The following is the history of one of the cases reported by Dr. Thomson. The patient was a young man who suffered from headaches beginning at the occiput and extending to the temples; they generally came on about 11 A. M. daily, and gradually grew worse until they reached their acme about 4 o'clock in the afternoon, after which they subsided, without, however, entirely disappearing. His physician failed to check their increasing severity, although on one occasion he administered thirty-grain doses of chloral with thirty grains of potassium bromide every two hours for two doses, with little more effect than a slight drowsiness being produced. The next day, the patient becoming maniacal from the pain, sixty-five grains of chloral, sixty of bromide and thirty of antipyrin were given within two hours. This caused a profuse sweating and moderate sleep. The third day a consultant was called, who recommended that quinine and Warburg's tincture (which had been tried at the beginning of the treatment) should be resumed in large doses. Accordingly, sixty grains of quinine and two ounces of Warburg's tincture were given in twenty-four hours, with even worse afternoon paroxysms of pain than before. The next day the bromide, antipyrin and chloral were resumed, but no great relief was obtained. At this time he was seen by Dr. Thomson, who recom-

mended drachm doses of fluid extract of ergot every hour for three doses, combining the first two doses with ten grains of quinine, and if his stomach rejected either of the doses, that the medicine be given per rectum. Soon after taking the first dose, the patient experienced a good deal of relief; the second dose was vomited, whereupon it was given per rectum, and this was soon followed by a complete subsidence of the pain, with profuse perspiration. This medication was repeated for three successive days, with final cure of the headaches. The second ten grains of quinine produced decided symptoms of cinchonism.

DR. JOSEPH COLLINS said that he has recently had occasion to try ergot in several cases. In one case the patient had been given huge doses of Warburg's tincture, quinine, bromide, and potassium iodide without any benefit. He was then given drachm doses of ergot, and a marvellous improvement at once followed. This was three months ago, and the man has had no return of the symptoms since. In another case the patient was a lady, aged forty years, who had long been under treatment for migraine, the pain being of a boring character and very difficult to relieve. In this case the value of ergot in the treatment of this affection was discovered accidentally; it was given to check a menorrhagia, and at the same time it relieved the headaches.

DR. THOMSON, in reply to a question, said our present knowledge is not definite enough to form any idea as to how ergot acts in these cases. He simply gave it as an empirical remedy. Furthermore, his paper refers entirely to neuralgias that are definitely periodical. These are usually very severe, and entirely different from the ordinary intermittent headaches. He referred to the fact that quinine, even in small doses, when it is combined with ergot, appears to produce cinchonism much more quickly than when given alone. In only one of the cases reported was there any antecedent history of malarial infection; in that case the patient simply gave the history of having resided in a malarious district. Very likely there was a malarious element in the other cases, of which the nervous symptoms were the only manifestations. Dr. Thomson also referred to the fact that intercostal neuralgia is often accompanied by sciatica; also the occurrence of sciatica after pleurisy. The latter combination he has noticed in about twenty cases.

Recent Literature.

Lectures and Essays on Fevers and Diphtheria, 1849 to 1879. By SIR WILLIAM JENNER, Bart., K.C.B., etc. New York: Macmillan & Co. 1893.

The papers which go to make up this volume were originally published during the thirty years between 1849 and 1879 in various journals and in the transactions of societies, and are now collected together for the first time by the author.

The most interesting and important of these papers are those early ones, published first in 1849-50-51, on the identity or non-identity of typhoid and typhus fever, and on the four febrile processes — typhus, typhoid, relapsing fever and febricula — at that time still commonly confounded in England under the term continued fever. Jenner's name is associated with the solution of this question in England, as were those of

Louis and Valleix in France, and those of Gerhard, Jackson, Stillé and Shattuck in this country. He followed the others at a considerably later period, and was preceded in his own country by Stewart of Edinburgh. Still, when Jenner did put his hand to the subject, his arguments were based upon a large and careful experience, and he treated it in a thorough and masterly manner, which finally forced the conviction of his contemporaries. It is well that these papers should be brought together in this form, that they may be made accessible to the present generation, who can thus realize how slowly a scientific truth which is to-day accepted as almost self-evident, won its way.

The well-known and excellent address delivered in 1879 before the Midland Medical Society at Birmingham, on the treatment of typhoid fever, is another of these contributions. Another series is formed by the Gulstonian Lectures for 1853, before the College of Physicians of London, on the acute specific diseases. The remaining pages are devoted to two lectures delivered in 1861 on diphtheria, and a clinical lecture delivered in 1875 on croup.

On Contractions of the Fingers and on "Hammer-Toe." By WILLIAM ADAMS, F.R.C.S., Eng., Consulting Surgeon to the Great Northern Hospital, etc. Second edition; 154 pages with eight plates and thirty-one wood engravings. London: J. W. A. Churchill. 1892.

This work comprises four essays, the first of which describes the deformity known as Dupuytren's contraction, the second and third "hammer-toe," and the last a method to remove or relieve depressed cicatrices. The first edition was published in 1879; the text has now been somewhat altered and new illustrations added. There is a *résumé* of the work done in England and America during the past ten years; and the description of "hammer-toe," with its treatment, has been introduced. The chapter describing the treatment of depressed cicatrices appeared in the first edition in almost the same form as now. The present edition, in addition to the above, includes results and observations of the past ten years, collected not only in the writer's individual practice but also from the work of other surgeons. The book is well arranged and has a good index. It is a well-written and interesting treatise; and the excellent illustrations add much to its value.

Essentials of Minor Surgery, Bandaging, and Venereal Diseases. By EDWARD MARTIN, A.M., M.D., Clinical Professor of Genito-Urinary Diseases, Instructor in Operative Surgery, etc., University of Pennsylvania, etc. Second edition, revised and enlarged, with 78 illustrations. Philadelphia: W. B. Saunders. 1893.

This little work, which is already well known, is one volume in the series known to medical students as the Saunders Question Compend; and treats of bandaging, certain details relating to minor surgical work, and venereal diseases. The present volume is a second edition, and has been revised to date. The illustrations show many changes; and those relating to bandaging are entirely new, the method used in the "American Text-Book of Surgery" being followed. The value of the volume has been much increased by its revision; and it contains much, in a very concise form, of interest to the practitioner and student.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 1, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 83 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

DIPHTHERITIC PARALYSIS.

DIPHTHERITIC paralysis generally manifests itself from eight to fifteen days after recovery from the local symptoms, though it may be delayed to a later period; in very exceptional cases it has been observed during the first week. This paralysis exists in one-third of the grave cases, according to Roger's statistics; it is not a rare sequel of benign diphtheria. The onset is generally slow and insidious. There is first only a little *hesitation* of the motor functions; deglutition, walking and other movements become more and more difficult.

The place of election of the paralysis is the velum pendulum, where it generally begins, and where it sometimes remains localized. A slight pallor, a little slowing of the pulse, are the only disturbances of the general state which are then noted. The reflux of liquid aliments by the nares indicates the impediment to deglutition. Extension of the paralysis to the pharynx generally supervenes, and the food can only be swallowed after repeated attempts, which soon fatigue the patient, and sometimes result in the refusal to take nourishment. Loss of voice testifies to paralysis of the larynx. The muscles of the eyes, of the neck, of the trunk, of the upper and lower extremities, of the rectum and bladder, even the special senses, are taken in the more complete forms of paralysis. More rarely the paralysis will attack the lower limbs before affecting the larynx and the tongue; and in a few cases it has been known to begin with the arms, then invade the soft palate and œsophagus, to attack finally the lower extremities.

It is a common experience to see troubles of vision supervene which are attributed to a fault of accommodation. The sight is enfeebled in different degrees, which may vary from slight amblyopia to complete blindness; there is hypermetropia, mydriasis, and, if but one eye is affected, inequality of the pupils. Almost all of the eye-muscles may be affected in turn.

The lower extremities generally begin to be paretic when these ocular troubles exist. The paralysis of the legs generally assumes the form of an incomplete

paraplegia. It is announced by formication and numbness in the legs. Walking becomes uncertain; the patient has an incomplete perception of the ground under his feet, and finds it especially difficult to go up and down stairs, or walk in the dark. A peculiarity of this form of paralysis is that the loss of motility in the feet and legs is never complete; the patients can move along by dragging or sliding their feet. When they are confined to their bed the lower limbs still preserve considerable power of movement, but without energy or much certainty. Jaccoud calls it an ataxy of movement, rather than paralysis. These ataxic symptoms, in conjunction with the abolition of the patellar reflex and the eye troubles, may give rise to a form of pseudo-tetanus. Contracture is very rare. The affected muscles present the ordinary reaction of degeneration; there is augmentation of the galvanic and diminution of the faradic contractility.

With regard to the condition of the hands, these become awkward and clumsy; patients drop or upset objects which they attempt to handle; tremblings resembling the tremors of paralysis agitans are frequently present. The muscular enfeeblement may be so great that the patient cannot feed himself. Paralysis of the face is a rare phenomenon. Bourges,¹ who has written a very complete description of the diphtheritic paralysis, and from whom we have here borrowed, gives a graphic account of cases which he has witnessed when the syndrome of labio-glosso-laryngeal paralysis was perfectly reproduced; the tongue, lips, cheeks, larynx being simultaneously affected.

Troubles of the sensibility are very frequent in diphtheritic paralysis, and almost always have to do with the regions affected with akinesic troubles. The ordinary alteration of sensibility is anæsthesia; exceptionally there is hyperæsthesia which manifests itself in the lower limbs by numbness and formication, and generally precedes the akinesia. Frequently the anæsthesia when it exists does not extend above the knees and elbows, but it may be general. It is sometimes accompanied with analgesia so complete that (Bourges says) cutting operations have been performed without ether. The anæsthesia may affect the lips, tongue and cheeks, and in rare cases the special senses, hearing, smell and taste have been abolished. The speech is often hesitating, stammering.

A capital fact in diphtheritic paralysis, says this same writer, and one that distinguishes it from all other paralyzes by peripheral neuritis, is that there is no muscular atrophy; the paralyzed limbs always retain their normal aspect and volume.

In very rare instances, the velum pendulum is not affected, and the disease is located in one muscular group or region without affecting other groups or other parts. Such are the cases where the paralysis has taken the paralytic or hemiplegic form, where it is limited to the eye muscles, to an arm, a leg, a hand, etc. Cases complicated with diaphragmatic paralysis are especially dangerous.

¹ H. Bourges: La Diphthérie, Paris, 1893.

In the localized and partial form, the paralytic accidents may be transient, and disappear in a few days. When the paralysis is general, its course is slow, lasting sometimes weeks and even months. Diphtheritic paralysis generally terminates in recovery (eight times out of ten, according to Bourges). In favorable cases, the power of movement reappears first in the lower limbs, then in the throat, then in the arms and hands, the trunk, the viscera and the eyes. Generally, the organs to be first paralyzed are the first to get well, but there is no fixed rule even here, and it often happens that the velum pendulum is the first part to be affected, and the last to resume its functions.

We have said nothing about those forms of infectious paralysis in which the heart and respiratory muscles are affected. These varieties are much more grave, for death then occurs often from syncope or asphyxia.

These paralytic results of diphtheria have been reproduced in animals in the experiments of Roux and Yersin.

THE ACTION OF PERMANGANATE OF POTASSIUM IN RENDERING MORPHIA INERT.

At a meeting of the medical and surgical staff of the West Side German Clinic, 42d Street, New York, Dr. William Moor, one of the physicians to the clinic, recently gave a demonstration on his own person of the efficacy of permanganate of potassium as an antidote for morphia. Against the earnest protestations of those present, he swallowed three grains of sulphate of morphia in solution, and immediately afterwards he drank a solution of four grains of the permanganate in four ounces of water. He was carefully watched, but none of the ordinary effects of morphia on the system were observed, and he has since stated that he experienced no ill effect whatever from the poisonous dose taken.

Dr. Moor, who has made a special study of therapeutics and toxicology, is twenty-eight years of age, and an Austrian by birth. He studied two years in Berlin and one in Paris, and is a graduate of the College of Physicians and Surgeons, New York. He states that previous to the demonstration mentioned he had experimented with rabbits, and also on his own person. He at first took an eighth of a grain of morphia, then a quarter of a grain, then half a grain, and finally three-quarters of a grain; and when he took permanganate of potassium afterwards there was no apparent toxic effect from the morphia.

In his demonstration at the German Clinic he would have been perfectly willing, he says, to take six grains of morphia, instead of three. Morphine, or any of the salts of opium, he claims, is immediately rendered harmless by contact with the permanganate. The antidote at once seeks the poison, passing by the other substances in the stomach. The soluble salt is acted upon by the permanganate 75,000 times more quickly than albumen, and several thousand times more quickly than peptone. Of course, the antidote should be ad-

ministered as promptly as possible after the morphia is taken.

Since this demonstration it has been claimed that the honor of the discovery is really due to Dr. William Condy, of London, and that Dr. J. B. Mitchell and other writers have referred to the efficacy of permanganate of potassium as an antidote; but, at all events, it is certainly true that its action in this regard has never been generally recognized by the profession. Lacerda recommended permanganate as an antidote to serpents' poison. Experiments indicate that it destroys the constitution of such poisons when brought into direct contact with them, but, when introduced into the general system, does not control their action.

Dr. Moor is now engaged in making a series of experiments to test the power of the permanganate as an antidote against strychnia, cocaine and other poisons. In the case of the first named, its action is said to be much slower than upon morphia.

Morphia is well known to be a powerful reducing agent, and it is doubtless by oxidation that the permanganate acts. As with serpent poison, so with morphia, it is undoubtedly essential that the permanganate should enter into direct contact with it. After the morphia has been absorbed the permanganate can have no action upon it. This physiologico-chemical restriction necessarily limits very much any value as an antidote which it may be proved that it possesses. Really, as we have already hinted, the most surprising thing about this incident which has attracted much attention in the daily press, is the fact that the action upon each other of two substances whose properties are so well known as are those of morphia and permanganate, should not long since have been accurately determined and described and been generally recognized. As a matter of fact, the usual therapeutic text-books and toxicologies are silent on this subject.

MEDICAL NOTES.

HONORS TO DR. BILLINGS.—Dr. Billings, Surgeon-General of the United States Army, has been elected an honorary member of the Royal Academy of Medicine of Belgium, and also a member of the International Statistical Institute, whose headquarters are at Rome.

PHYSICIANS IN THE VIRGINIA LEGISLATURE.—It is a little unusual to find physicians actively engaged in politics; but there are eight physicians in the present legislature of Virginia. Seven of them are Fellows of the State Medical Society.

APPOINTMENT TO THE CHAIR OF MIDWIFERY IN GLASGOW.—Dr. Murdoch Cameron has been appointed to the chair of Midwifery in the University of Glasgow.

EIGHT INSANE PATIENTS BURNED TO DEATH.—The building on the Boone County (Iowa) Poor Farm used as an insane asylum was burned to the ground

January 23d, and eight of the nine inmates were burned to death. Four of the patients were locked in their rooms, and could not have escaped even if they had tried. The others were not intelligent enough to try, and were surrounded by fire before help could reach them.

THE LETTSOMIAN LECTURES. — The Lettsomian Lectures this year are now being given by Mr. Frederic Treves, F.R.C.S., who has chosen "Peritonitis" as his subject.

"THE GRAND OLD MAN" OF MEDICINE. — The *Medical Press and Circular* gives a new title to the Autocrat of the Breakfast Table in the following bit of news. It would lead its readers, however, to infer by analogy that Sir Spencer Wells had written the poems of Thomas Hood.

"The 'Grand Old Man' of Medicine seems to be Dr. Oliver Wendell Holmes. The College Club, of Boston, recently gave a reception in his honor, and about five hundred persons were presented to him. He received them as he sat 'in a laurel-decorated chair under a bower of palms.' During the course of the proceedings Dr. Holmes recited 'The Last Leaf,' 'Dorothy Q.,' and 'The Chambered Nautilus,' all of which must have been intently listened to. Truly, we have no one in this country, of similar standing belonging to the profession, who could perform such a feat. Fancy Sir Spencer Wells, for example, reciting 'The Dream of Eugene Aram' at the *conversations* of the Medical Society!"

THE HARVARD MEDICAL SOCIETY OF NEW YORK CITY. — At the meeting held on January 27th, the following officers for 1894 were elected: President, Reynold W. Wilcox, M.D.; Vice-President, Royal Whitman, M.D.; Secretary and Treasurer, Dillon Brown, M.D.; Executive Committee, J. Winken Brannan, M.D., Frank H. Daniels, M.D., and Howard Lillenthal, M.D.

BOSTON AND NEW ENGLAND.

SMALL-POX IN BOSTON. — During the week ending at noon, January 31st, there was one death from small-pox. No new cases have occurred.

A BEQUEST TO THE CHILDREN'S HOSPITAL OF BOSTON. — The will of Mr. C. C. Gilbert, of Bridgewater, bequeaths the sum of \$3,000 to the Children's Hospital of Boston.

SMALL-POX IN MASSACHUSETTS. — During the week ending at noon, January 31st, there were reported to the State Board of Health three cases of small-pox from places outside of Boston, one each from Lowell, Brookline and Worcester.

SALEM HOSPITAL REPORT. — During the year just closed there were treated in the Salem Hospital 318 patients: 178 medical, and 140 surgical. There were 153 males and 165 females.

TYPHOID FEVER AT LOWELL, MASS. — Since the first of the year, seventy-three cases of typhoid fever have been reported to the Board of Health in Lowell,

and during the last week many new cases have occurred. The prevalence of the disease is ascribed to the use of Merrimac River water, since in two wards which are supplied with water from the driven wells in experimental operation, there is scarcely any typhoid. Those who are ill in these districts have been at work in quarters where the river water only is supplied.

VACCINATION IN VERMONT. — The State Board of Health of Vermont, at its meeting in Burlington last week, voted to recommend a general vaccination throughout the State, in consequence of the prevalence of small-pox in Boston and New York and the signs of scattered infection in other New England places.

NEW YORK.

RED LIGHT ON SMALL-POX. — It is announced that one of the small-pox pavilions at the Riverside Hospital on North Brother Island is to be fitted up with red-glass windows, and with red-glass globes for the lights used at night, in accordance with the alleged discovery that the skin of small-pox patients is extremely sensitive to the violet-colored rays of light, and that it is these which give rise to the pitting. The experiments which it is claimed demonstrated this fact was made by Dr. Lindholm and Finsen, in the City Hospital at Bergen, Norway, and was detailed in a recent article in this JOURNAL (January 11, page 35). New York will therefore be the first city in this country to try the efficacy of the red light, which is the same as that used by photographers in developing sensitive plates.

SMALL-POX ON THE INCREASE. — Small-pox seems to be on the increase, and several cases have recently been reported from charitable institutions in the city and on the islands, as well as at Charity Hospital, Blackwell's Island.

DIPHTHERIA. — There has been a considerable increase in diphtheria this season as compared with last year. From the 1st of January to the 24th there were reported 767 cases as against 382 in the same period in 1893. The mortality is said to be about 33 per cent.

A NEGRESS WHO KNEW WASHINGTON. — There recently died at the Colored Home and Hospital on First Avenue a negress by the name of Sullivan, at the extreme age of 107 years. The correctness of her age is said to be attested by a Bible in the possession of her son, who is now over 65 years old. The life of this ancient woman is quite an interesting one. She was the daughter of Philip Pickering, who fought under Gen. Francis Marion in the War of the Revolution. She was born a slave in the Carroll family, in 1785, and in later days often recalled a visit made with her master and mistress to General Washington, at Mount Vernon. By the dying request of her mistress, she was given her freedom, and she then removed to Washington. Here she entered the service of the Buchanan family, and on one occasion had the honor of waiting upon the guests at a banquet given to

La Fayette, who personally complimented her. She was married in Washington, and in 1829 removed to New York. One of her brothers fought under General Jackson at the battle of New Orleans, and when the latter became President, he gave him a position as assistant gardener at the White House.

Miscellany.

EXTERNAL INDICATIONS OF INHERITED LONGEVITY.

THE December meeting of the New York Academy of Medicine was devoted to a discussion of various factors influencing longevity, either directly or relatively. Dr. Morris, in speaking of the constitutional inheritance, said that in most cases the line of inheritance could be very fairly determined by the careful observation of certain external indications—as color, motions and measurements.

“One of the most certain indications of long or short life was the size of the head, for in the brain lay the great centre of power. A person with a head whose diameter at the thin portion of the temporal bones measured five and a half to six inches was almost sure to give a longevity on the father's side of seventy to ninety years or over. If the head measured in front from the external auditory canal to the naso-frontal suture as much as four and three-fourths or five inches, we might be almost sure of long life on the maternal side. A beard which was darker or redder than the hair, indicated inheritance from the paternal side; if it were lighter than the hair, the inheritance was probably from the maternal side.”

THE NEW RATIONAL WAY TO SLEEP.

DR. WILHELM FISCHER, according to *La Médecine Moderne*, has recently completed some researches into the proper method of sleeping. He says that to sleep well, that is, to obtain the quickest and surest intellectual rest, a person should lie with the head low and the feet elevated at least to the horizontal. The ordinary method is entirely wrong. The difficulty in becoming used to this proper method of flushing the brain to rest is not so very great if one has patience to begin gradually. “Each fortnight the sleeper is to discard one pillow until he can sleep on a level.” The time required for this is not stated. It must depend upon the number of pillows started with; and from the manner of mention this might be many dozen. But, to return to the directions; after being accustomed to the level position, the would-be-sleeper-*comme-il-faut* places his feet each night in a higher plane than his head, increasing the incline by adding the discarded pillows until finally he slumbers peacefully with his head on the mattress and his feet on many pillows.

This attitude has, he says, “a marvellously curative effect on many diseases, especially in nervous and anæmic patients; but its real and crowning triumph is in the treatment of varicose veins, hæmorrhoids, floating kidney, basic pulmonary disease and erotic dreams.”

If this highly rational way of sleeping becomes as general as it should, we may expect to see a new style of bedsteads put upon the market built like the kangaroo, with long legs at the lower end.

THE PLEASURES AND REWARDS OF A PHYSICIAN'S LIFE.

IN his commencement address at Lafayette College last June, Dr. William W. Keen, of Philadelphia, gave the following picture of the pleasure and satisfaction of the busy physician, which we reprint at the request of another eminent professor:

“Sir Spencer Wells, as the net result of his first 1,000 ovariectomies added 20,000 years to human life; and so far has modern surgery surpassed this result that every thousand similar operations to-day adds not less than 80,000 years to human life! Think what one of these lives means, as the pale cheek regains its color, the feeble pulse its force, strength succeeds weakness, each day records a gain, and finally health is re-established. The tender father returns to his usual pursuits; the adored mother once more becomes the centre of loving care of her family; the beloved child is restored to the family circle with ruddy health, rescued from the valley of the shadow of death itself. The hushed voices, the soft tread of the sick-room have given place to the laughter of health; the mists of sorrow are driven away; the anxious alarms of disease have vanished. What, think you, can equal the joy of the physician, as he views this happy transformation? Who is a dearer, more cherished, more welcome friend than he? Who finds a warmer place by the fireside and in the very hearts of his patients? No one can adequately appreciate his profound joy, his daily delight, his deep gratitude to the ‘Giver of every good and perfect gift.’ Oh, my friends, it is a blessed profession, a divine calling, with a heavenly recompense on earth!”

THE SOLUTION OF THE NEGRO RAPE PROBLEM.

THE solution of the yearly more serious problem of negro rape in the South is a most difficult but important task. Lynching, with its attendant tortures, has proved as useless as it is atrocious.

In the November number of the *Virginia Medical Monthly*, Dr. Lydston strongly advised legal castration as a remedy; and he is supported in a more recent issue of the *Texas Medical Journal*, by Dr. Daniel. The quieting effect of this treatment upon each criminal would, of course, be efficient for that one man, but it is doubtful how far it would carry a deterrent warning to other negroes in the blinding heat of lust.

Dr. P. C. Remondino, in the January number of the *National Popular Review*, urges the adoption, not of expiatory laws, but of preventive legislation. It is not rational, he claims, to look upon the unbridled licentiousness of the negro as solely a racial trait. The negro child, especially the male, is subject to many nervous disorders from slight irritation, and this characteristic he carries with him to adult life. Accordingly, Dr. Remondino sees in the removal of “an irritating and ulster-proportioned prepuce” the efficient and gentle means of stopping the sexual crimes and improving the moral system of the negro race. He says:

“Although the male Jews are much given to unholy and unedifying carnal pursuits, and in that field make records only equalled by the great Nimrod as a hunter, still, we never hear of a Jewish rapist.

“From our observation and experiences in such cases, we feel fully warranted in suggesting the whole-

sale circumcision of the negro race as an efficient remedy in preventing the predisposition to indiscriminate raping so inherent in that race. We have seen this act as a valuable preventive measure in cases where an inordinate and unreasoning as well as morbid carnal desire threatened physical shipwreck: if in such cases the morbid appetite has been removed, or at least brought within manageable and natural bounds, we cannot see why it should not—at least in a certain beneficial degree—also affect the moral stamina of a race proverbial for the leathery consistency, inordinate redundancy, generous sebaceousness and general mental suggestiveness and hypnotising influence of an unnecessary and rape, murder and lynching breeding prepulse. It would certainly be more humane for a State legislature to pass an act legalizing and enforcing circumcision as a preventive measure, just as it would enforce either vaccination or quarantine regulations, than to enact laws to castrate or eunuchise the accused after his infraction of the law."

Correspondence.

THE PREVALENCE AND RECOGNITION OF SCABIES.

BOSTON, January 25, 1894.

MR. EDITOR: In the JOURNAL of September 16, 1886, a paper entitled "Clinical Notes on Scabies," by Dr. F. B. Greenough, was published, in which mention of the increased prevalence of the itch was made, and the suggestion offered that it might be well for boards of health to consider measures looking toward its control.

In the JOURNAL of February 7, 1889, there appeared an article by Dr. J. C. White, on "The Increasing Prevalence of Scabies," which needs no comment.

Lastly, in the JOURNAL of October 19, 1893, under the heading of "The Increasing Prevalence of the Itch," the statistics of Dr. Stelwagon, of Philadelphia, are quoted, as bearing upon this point.

Since the publication of Dr. White's and Dr. Greenough's papers, scabies has continued to present itself at the hospital clinics with great frequency, and often four or five new cases are recorded in a single morning. In private practice also it is in no sense a rarity, and instances of its occurrence in people of the best social class are not unusual. The importance of recognizing scabies cannot therefore be overlooked; and the conviction that a great deal of annoyance and suffering, as well as in some measure the propagation of the disease, might be avoided by prompt treatment, has led me to add my voice to those of my colleagues.

It is true that scabies, especially in a cleanly person, may sometimes offer much perplexity to the diagnostician; yet these cases are always in the minority, and even in them it is usually possible to decide the question by treatment.

The point to be borne in mind, it seems to me, is that in any itching affection, where marks from scratching or eczematous appearances are present to however slight a degree, the possibility of scabies should be entertained and excluded, before the patient is allowed to go on his way with a prescription for a mild antipruritic lotion, and perhaps a favorite tonic internally.

The frequent failure to recognize is undoubtedly due to the increased prevalence, and to the false presumption that scabies is almost unknown in cleanly people. Formerly, as Dr. White has stated, it was almost impossible to find sufficient material for class demonstration. For these reasons largely, this common affection is now frequently unrecognized, and apparently unsuspected, by practitioners of the highest medical attainments.

JOHN T. BOWEN, M.D.

METEOROLOGICAL RECORD.

For the week ending January 20, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer	Thermometer		Relative humidity		Direction of wind.		Velocity of wind.		Weather.		Rainfall in inches.

Deaths reported 2,399; under five years of age 869; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 341, acute lung diseases 566, consumption 289, diphtheria and croup 163, measles 33, typhoid fever 29, scarlet fever 28, diarrhoeal diseases 23, whooping-cough 21, cerebro-spinal meningitis 17, erysipelas 11, small-pox 11, malarial fever 5.

From measles New York 24, Milwaukee 4, Brooklyn 3, Boston and Nashville 1 each. From diarrhoeal diseases New York 11, Fall River 3, Boston and New Bedford 2 each, Milwaukee, Portland and Salem 1 each. From whooping-cough New York 3, Pittsburg 5, Brooklyn 3, Boston and Cincinnati 2 each, Brookline 1. From cerebro-spinal meningitis New York 8, Cleveland 4, Brooklyn 2, Worcester, New Bedford and Everett 1 each. From small-pox New York 6, Boston 3, Lowell 2. From ery-

apeles New York 5, Boston 3, Brooklyn 2, Somerville 1. From malarial fever New York and Nashville 2 each, Pittsburg 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending January 13th, the death-rate was 28.6. Deaths reported 5,726; acute diseases of the respiratory organs (London) 762, whooping-cough 219, measles 108, diphtheria 78, scarlet fever 52, fever 47, diarrhoea 36, small-pox (Bradford 3, Birmingham 2, London, West Ham and Nottingham 1 each) 8.

The death-rates ranged from 19.5 in Gateshead to 50.2 in Norwich; Birmingham 31.6, Bradford 21.9, Cardiff 24.2, Halifax 23.0, Leeds 27.0, Liverpool 33.3, London 29.5, Manchester 30.8, Newcastle-on-Tyne 20.7, Plymouth 55.7, Sheffield 24.8.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 20, 1894, TO JANUARY 26, 1894.

FIRST-LIEUT. EUCLID B. FRICK, assistant surgeon, U. S. A., is relieved from duty at Fort Keogh, Montana, and ordered to Fort Townsend, Washington, for duty at that post, relieving CAPTAIN ROBERT R. BALL, assistant surgeon.

CAPTAIN BALL, on being relieved by FIRST-LIEUT. FRICK, will report in person to the commanding officer, Fort Monroe, Virginia, for temporary duty.

FIRST-LIEUT. MADISON M. BREWER, assistant surgeon, will, upon the arrival of CAPTAIN BALL, be relieved from temporary duty at Fort Monroe, Virginia, and will return to his proper station, Fort Riley, Kansas.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 27, 1894.

J. L. NEILSON, surgeon, from Naval Medical Examining Board and to Boston Navy Yard.

R. A. MARMION, surgeon, from Boston Navy Yard and to Smithsonian Institution.

C. U. GRAVATT, surgeon, from Smithsonian Institution and to the "Dale."

E. H. GREEN, surgeon, from the "Dale" and to the "Marblehead."

A. C. H. RUSSELL, passed assistant surgeon, ordered as member Naval Medical Examining Board.

T. A. BERRYHILL, passed assistant surgeon, ordered to duty at Naval Laboratory and Department of Instruction.

H. J. BABIN, surgeon, ordered as member of Board of Inspection Survey.

F. L. DuBois, medical inspector, and C. A. SIEGFRIED, surgeon, appointed delegates to the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIVE WEEKS ENDING JANUARY 20, 1894.

BAILHACHE, P. H., surgeon. Detailed by the president as delegate to International Sanitary Conference in Paris, France. January 15, 1894.

SAWTELLE, H. W., surgeon. Detailed as chairman, Board for physical examination of officers, Revenue Marine Service. January 19, 1894.

AUSTEN, H. W., surgeon. To represent the service at International Medical Congress, Rome, Italy. December 16, 1893.

STORER, G. W., surgeon. Granted leave of absence for seven days. December 22, 1893.

LEWIS, FAIRFAX, surgeon. To proceed to St. Petersburg, Russia, for duty. December 28, 1893. To proceed to Paris, France, for temporary duty. January 16, 1894.

CARTER, H. W., surgeon. To report at Bureau for temporary duty. December 17, 1893.

BANKS, C. E., passed assistant surgeon. Detailed as recorder, Board for physical examination of officers, Revenue Marine Service. January 19, 1894.

PECKHAM, C. T., passed assistant surgeon. Granted leave of absence for seven days. January 6, 1894. Granted leave of absence for six days. January 11, 1894.

GLENNAN, A. H., passed assistant surgeon. Granted leave of absence for five days. December 20, 1893.

BROOKS, S. D., passed assistant surgeon. To proceed to Sandusky, Ohio, as inspector. January 17, 1894.

WHITE, J. H., passed assistant surgeon. Granted leave of absence for thirteen days from December 18, 1893.

—, passed assistant surgeon. Granted leave of absence for thirteen days from December 18, 1893.

WILLIAMS, L. L., passed assistant surgeon. Granted leave of absence for fourteen days. January 17, 1894.

BRATTON, W. D., passed assistant surgeon. To proceed to Wilmington, N. C., for duty. January 9, 1894.

WOODWARD, R. M., passed assistant surgeon. Granted leave of absence for ten days. December 18, 1893. Granted leave of absence for fourteen days. January 17, 1894.

STORER, J. B., passed assistant surgeon. To proceed to Marshfield, Oregon, as inspector.

GUIERAS, G. M., passed assistant surgeon. To proceed to New Orleans, La., for duty.

PERRY, J. C., passed assistant surgeon. To proceed to Norfolk, Va., for temporary duty.

YOUNG, G. B., assistant surgeon. Granted leave of absence for three days. January 1, 1894.

BROWN, B. W., assistant surgeon. Granted leave of absence for thirty days. December 16, 1893.

ROSENAU, M. J., assistant surgeon. To proceed to Evansville, Ind., for temporary duty. January 13, 1894.

GARDNER, C. H., assistant surgeon. To proceed to San Francisco Quarantine for temporary duty. December 22, 1893.

NYDEGGER, J. A., assistant surgeon. Granted leave of absence for twenty-three days. December 20, 1893.

OAKLEY, J. H., assistant surgeon. Granted leave of absence for twenty-five days. December 20, 1893.

NORMAN, SEATON, assistant surgeon. Granted leave of absence for thirty days. January 15, 1894.

PROCHAZKA, Emil, assistant surgeon. To proceed to Louisville, Ky., for duty. December 26, 1893.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held at 19 Boylston Place, on Monday, February 5th, at 8 o'clock.

Dr. Charles M. Green: "Four Unusual Cases: (1) Imperforate Hymen, with Hematocolpos; (2) Cysts of the Vagina; (3) Recto-vulvar Fistula; (4) Salivation of Pregnancy."

Dr. J. E. Goldthwait: "Some Observations upon the Etiology and Treatment of Anterior Metatarsalgia."

JOHN C. MUNRO, M.D., Secretary.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Surgical Section will hold its regular monthly meeting at 19 Boylston Place, February 7, 1894, at 8 o'clock.

Dr. Gardner W. Allen: "A Case of Litholapaxy."

Dr. E. H. Bradford: "Investigations of Flat-Foot."

Dr. Otis K. Newell: "The Intermittent Rapid Dilatation of Urethral Stricture."

CHARLES L. SCUDDER, M.D., Secretary, 1 Marlborough St.

RECENT DEATHS.

CHARLES COLBY PIKE, M.D., M.M.S.S., died in Peabody, Mass., January 27th, aged forty-nine years. He was born in New London, N. H. During the war he served in the Eleventh New Hampshire Regiment and was severely wounded at Fredericksburg. After the war he went to Dartmouth College, graduating in the class of 1869.

GEORGE TORREY GRIERSON, M.D., M.M.S.S., died in Lowell, January 28th, aged twenty-five years.

BOOKS AND PAMPHLETS RECEIVED.

Dr. G. Zander's Medico-Mechanical Gymnastics; Its Method, Importance and Application. By Dr. Alfred Leverlin. With a portrait of Dr. Zander, several explanatory illustrations and a map. Stockholm. 1893.

Liquor Sedans, Saw Palmetto, Damiana, Pichi and Stylosanthes Eliator; Their Uses in Nervous Diseases; Their Medico-Legal Relation; Epilogue. By John J. Caldwell, Neurologist, of Baltimore, Md. Reprint. 1894.

Descriptive Catalogue of the Anatomical and Pathological Specimens in the Museum of the Royal College of Surgeons of Edinburgh. By Charles W. Cathcart, Conservator, Fellow of the College. Vol. I. The Skeleton and Organs of Motion. Edinburgh: James Thin. 1893.

Climates of the United States in Colors. Popular edition of Denison's Charts, with additions. By Charles Denison, A.M., M.D., Denver, Colo., Professor of the Diseases of the Chest and of Climatology, Medical College, University of Denver; Ex-President of the American Climatological Association. Chicago: The W. T. Keener Co. 1894.

Lectures.

LECTURES ON SURGERY.

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XXIV.

DISEASES OF THE NOSE.

Epistaxis. — I will speak at once of the most common affection surgically that we have to treat in the nose, and that is epistaxis or nose-bleed. It comes from a variety of causes. In a certain proportion of cases it is wholesome and useful. It depletes very rapidly the venous sinuses at the base of the brain. There is a direct communication with the veins of the nose through the cribriform plate of the ethmoid and with the base of the brain; and in youth, in violent exercises, in persons who are plethoric, etc., moderate nose-bleeds frequently are useful, and if not excessive, need not excite anxiety. In old age, however, in elderly people, nose-bleed, when it amounts to anything, is frequently the sign of some congestion in the head which should warn us that the patient may be in danger of rupturing a vessel and having apoplexy. Nose-bleeds in old people are rather unfavorable signs as regards the prognosis of future life. Something is apt to take place after this warning is given; and we should be very careful about the diet and exercise of such patients. But nose-bleed only becomes injurious in younger subjects when they either are the subject of some other disease, a diseased condition of the blood or constitutional disease; or else when it becomes very frequently repeated, apparently from the state of anæmia, thinness of the blood and weakness of the walls of the veins. Typhoid fever, diseases which affect the blood, as purpura, or profound anæmia, are frequently associated with nose-bleed. Occasionally, as you know, it is merely vicarious, so to speak, occurring in the place of habitual discharges in other directions; especially the menstrual flow in the female is sometimes supplemented, or aborted, by the frequent occurrence of nose-bleed. So also, certain patients who have trouble about the rectum and bleed from piles, occasionally have this arrested, and then have epistaxis follow. This is not so severe, and should not be classed with those cases which are what is called true bleeders, where there is that peculiar constitution of the blood that it lacks the fibrinous sticky element, and cannot coagulate when thrown out from the vessels. These patients may bleed from any point: from the gums; mucous surfaces like the urethra, and sometimes from the skin, making a bloody exudation from the true skin. This is associated with a condition of the blood which is usually inherited. Such cases are not very frequent. They can hardly be classed as the ordinary accidents of nose-bleed. Any acute disease of the liver, which is going on to a fatal condition, is frequently followed by hæmorrhage; hæmorrhage by the nose and mouth and bowel is one of the common results. In typhoid fever, where the fever seems to expend itself and its force on the head and nervous system, bleeding from the head and nose seems to take the place of bleeding from Pylers' patches.

Ordinary nose-bleed need occasion no alarm. It is

best arrested by keeping the patient in the upright position, applying cold, avoiding stooping over; sometimes it can be arrested by keeping the hands above the head a little while; frequently by the application of cold to the spine, or cold over the forehead, or cold, in the form of pieces of ice held in the mouth, where it will press against the palate process. These measures are simple ones and are generally sufficient. When they are not sufficient, frequently the putting of a small plug of lint in the nostril which is bleeding, especially if it is dusted over with a little dried persulphate of iron, succeeds. Syringing out the nose with cold water is sometimes effectual. These measures are enough for simple cases; but the cases which excite alarm are those where the bleeding goes on almost without stopping, but with remission, for, perhaps, an entire day. The patient becomes gradually quite feeble and exhausted. The respirations are very much impeded by the enormous clots that form in the nasal passages, and which temporarily arrest the bleeding; but it keeps breaking out. If the patient lies down from faintness, the blood goes on trickling slowly backwards and large quantities of blood run down the pharynx, and are swallowed. Then, after a while, the stomach being distended by clots rejects these; vomiting comes on and that starts the nose-bleed again. So in one of these bad cases, I suppose, if they went far enough, a fatal result might ensue; though usually they are stopped before that result is reached.

Simple measures are of no use in these forms; and the most thorough way to arrest the bleeding is by plugging the nose, the anterior and posterior nares as well. Each nostril is a separate cavity. It is rarely that bleeding occurs from more than one nostril at a time: and the bleeding nostril is plugged front and behind, and the plugs left in thirty-six to forty-eight hours. Some surgeons advise leaving them three or four days. The objection is that they soon become very foul and offensive, and provoke ulceration of the membrane covering the delicate bones inside the nose; and may, if kept in long enough, lead to caries of the bone, and a chronic state of ozæna with filthy discharge. It is always a delicate matter to decide the time when the plug shall be taken out in a bad case; but, as a rule, by forty-eight hours an attempt must be made to remove it carefully; and if bleeding occurs, a fresh plug may be put in, which is clean and aseptic, and may be left in considerably longer. It is perfectly easy to plug the anterior nares. To get a plug behind in the posterior nares is impossible without a guide. That guide must be a thread passed through the nostril, behind the soft palate, out of the mouth. The patient must open his mouth widely, a gag is put between the teeth, and the thread is carried through by a little instrument called Belocq's sound. The sound is threaded, passed through the nose, and the finger passed into the mouth catches the thread and draws it out, and the catheter is withdrawn; the other end is out of the nose. We have the location we wish to plug under control with this string. To the end which comes out of the mouth, must be fastened another double thread, and to this a small piece of lint or sponge, not too large. If a sponge, it will swell to a certain degree; but the lint will not swell. That must be tied with a double thread, and then passed into the mouth, and guided with the finger behind the palate, and pulled firmly into the posterior nares, so that it will not drop back into the throat. Another plug is put in front, and a string tied over it,

¹ These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

so that the two are pulled together. The cavity between is gradually filled by coagula, and bleeding is necessarily arrested. The use of the two strings on the back, where the plug is attached, is to leave one coming out of the mouth, which can be fastened around the ear, and which is a guide to the posterior plug. This is important, because in removing the posterior plug we wish to do it with as little excitement as possible, and if we have no guide, we are forced to take a catheter, or something of that kind, and put it in the nose and dislodge the plug, and catch it as it drops in the throat; whereas if we have a string guide, we cut the anterior string, take out the anterior plug, and pull on the string in the back of the mouth, and easily withdraw the plug. This may make the difference between starting the bleeding, and having to plug over again. To our surprise we see how much suffering is produced by this plugging in the first twenty-four hours. At first the patient is relieved of bleeding, and he can take nourishment and lie down and sleep; but he soon has pain in the nose and face and eyelids. All the parts about the cheek begin to have an oedematous swelling to a very marked degree; and the skin of the nose is largely distended by swelling, and the patient looks as if he had an attack of facial erysipelas coming on. This is due to the pressure of the plugs; and if they are left in too long, it may be followed by septic consequences and dangerous results. On taking out the plugs, the swelling slowly subsides, and the case is over.

A little rubber arrangement, which is very like what we call the colpeurynter used to dilate the cervical outlet, can be used. That can be flattened out and with a probe or director passed in until it projects into the posterior nares in the throat. When it has got fairly through the nostril, it can be blown up with air firmly, and it makes a sufficient air plug to the passage. Of course, it adapts itself perfectly to the shape of the nasal cavity, and makes a very ingenious and neat plug. When we have one of these it is easier to use and to remove than the more clumsy method of the sponge. In many cases we shall be called to a distance, to a case of nose-bleed, without these preparations, and we need not wait for Belocq's instrument; but with a good strong elastic catheter we can accomplish in a few moments the arrest of the hæmorrhage.

Deviations of the Septum of the Nose. — The septum is partly bony and partly cartilaginous. The cartilaginous part is thin and elastic, and covered with delicate mucous membrane and vessels and nerves. This frequently grows out of place, sometimes probably in consequence of a blow, and sometimes by a spontaneous deformity which pushes it to one side and gradually occludes one nostril. This condition leads to catarrh, retention of secretions on the side where the occlusion is, to change of the voice. When the disease goes on a little longer, and is not treated, changes take place in the septum itself; and as the young person grows older the septum thickens and grows out bony ridges and spurs which project on the occluded side and still more obstruct the nose. The septum can be broken and forced back into place in the early stages of the affection. It will not, however, stay there, but recoils just like a piece of birch bark. It can only be forced to stay back by cutting through it, and destroying its elasticity. In more severe cases it is often best to saw off a piece of the septum with a fine saw on the occluded side. The spurs are sawed

off, and a piece of the septum sawed off. We may or may not go through. Sometimes we can succeed in sawing off the spurs without sawing through into the other side of the nose, sometimes not. If we saw through, a small permanent opening is left. If it is too small, it is sometimes accompanied by a whistling sound in breathing, which is annoying. If it is opened, it is better to make it of sufficient size, that the air may travel back and forth without making this sound.

The septum is the seat of ulcerations which used to be thought to be syphilitic. They frequently are tuberculous. The ulceration may go so far as to perforate the septum, and the patient has an opening through the septum which is frequently the size of a dime or lead pencil. It does not make any external deformity whatever. It does not make the nose of that peculiar shape that it does in syphilis, when the vomer is cast off by caries. There is an obstinate ulcer, with a little hole leading through. Local applications of various kinds, and constitutional treatment, are the best things that can be done. Usually granulations can be encouraged; and if the septum is not eaten through, the ulcer can be healed. If it is, the hole can be healed around the margin so that it will not expand, and the patient get along very comfortably. It is important to recognize the fact that many of these ulcerations are in perfectly innocent parties with regard to either primary or inherited syphilis; and that they are quite common in young and scrofulous subjects.

The cartilage will not stand any very violent applications. If you try to cauterize it, anything of that kind, you make the cartilage ulcerate and break down more. Cleanliness and mild antiseptics and constitutional treatment should be employed.

The turbinate bones grow out of place, grow exostoses, project into the passage and frequently obstruct the breathing. Portions are frequently cut away with benefit, and sometimes the trephine is used and the turbinate bones cut through, giving the patient much deeper breathing power. Since the use of the electric light and the rhinoscope to look into the nose, and the minute electric wire which can be heated as a cautery, it is easy to burn off portions of the delicate bones of the nose with safety and without much suffering. Ether is not necessary. In fact that is not desirable where the hot wire is used, because we are in danger of setting the ether on fire. Cocaine is all that is necessary to blunt the sensibility enough to do this sort of operation.

Foreign Bodies in the Nose. — In a child with trouble in the nose your first thought should be is there any possible foreign body concealed in the nose. Infants and children are very apt to put substances up in the nose, and those are generally of a character that cannot be got out easily; beans and peas and buttons are favorite objects. They are pushed up far enough to get beyond the inferior turbinate bone, and are there held; provoke constant discharge, and other signs of chronic ozæna, or polypus. The child is frequently brought to the doctor with the idea that it has polypus. Careful search will find something hard in the nose; and the nose sprayed with cocaine and made non-sensitive, the foreign body can be got out, and the case is speedily cured.

Polypi in the Nose. — Polypi in the nose are of two forms. The common form is a soft, gelatinous polypus which grows from the turbinate bones, and sometimes

in extreme cases extends its growth up in little colonies of polypi which grow as high as the upper turbinate bone and even as high as the ethmoid. The ordinary soft polyp is attached to the inferior turbinate bone, floats or hangs in the nasal cavity, rises up and down with the movements of respiration. If the patient makes a forced expiration through the nose with the mouth shut the polypus can generally be brought into sight, and is seen lying as a white, soft, gelatinous-looking mass a little ways up the nasal cavity. Or when the patient inspires violently, it is drawn behind the turbinate bone and sometimes when it is large passes back of the posterior nares and hangs back into the throat. In extreme cases they protrude down the throat, and if the patient has the mouth held widely open and raises the palate by saying the word "ah" the polypus can be seen projecting in the throat behind the palatine arch.

The mucous polypus can be readily removed; but unfortunately this frequently does not permanently cure the affection. The tendency having been developed to their growth, others form. They are slow to form. They frequently do not show signs of returning for six months, but they are apt to come back. The nearest way to remove them is to locate them exactly by the aid of the mirror and remove by the snare or hot wire. If we have not this means, we can follow up the polyp and get hold of the stem and twist it off. It frequently brings away a little of the turbinate bone with it. This does no harm; and by removing the periosteum and root on which the polyp grows, that particular polyp is exterminated, and has no chance of starting again. We must not be satisfied with one search; but put the forceps throughout the nose, and frequently we succeed in extracting one large one, and two or three small ones. After a few days, when bleeding has subsided and the soreness gone, the nose can again be treated with cocaine, and investigated carefully with the lamp and mirror, to see if any others are left.

The signs of polyp are usually those of chronic catarrh and obstruction. They change in their shape and size; swell up with fluids and collapse again according to different states of the system; and where the patient has a slight cold and congestion, it increases the flow of blood to the mucous membranes and distends the polyp. A chronic catarrh running from the nose; accumulation of secretion; difficulty of breathing; snoring in the sleep, are signs of polypus. When enlarged they distend the nose, but must be of considerable size to do so.

On examination, the two sides of the nose do not correspond. In extreme cases the nasal bone becomes displaced to some degree as well as the cartilage, so that the nose is entirely flattened out on that side. These are unusual cases.

Ordinary soft, gelatinous, nasal polypi then are usually removed by one of these methods. Subsequently the nasal cavity must be treated by injections of weak carbolic acid and by astringents. Quinine sometimes is very useful; and various agents to endeavor to prevent the return. The milder forms of spray are the best to use in this cavity. The nasal douche, which is merely a repetition of the fountain syringe, is no longer thought to be as desirable as it used to be. It is too violent, too forcible, has occasionally made trouble by distending the Eustachean tubes, and has brought on affections in the middle-ear by being too forcibly

used. It is only in extreme cases of filthy ozæna, and where other measures will do no good at all, that the nasal douche is to be used. It is better to use the applications in the form of spray, applied both behind by the throat, and forward through the nose.

The person who has once had a mucous polypus must be on the lookout for others; and when the slightest signs present themselves, he should be inspected and the growths taken out, if possible. With the cauterizer the bases from which they grow, can be thoroughly destroyed; and, sometimes, after one or two operations, no more recur. Sometimes they recur after long intervals.

The other form is essentially a fibrous tumor, and is called sometimes the naso-pharyngeal polypus because it affects the posterior nares and the top of the pharynx. It grows sometimes from the edges around the nasal cavity, the little hollow of the pterygoid process; and sometimes about the posterior septum of the nose; and frequently, also, from what is called the occipito-sphenoid bone, the junction of the sphenoid and occipital at the true base of the skull. This, of course, is at the very top of the pharynx, and covered with mucous membrane; it is in a pouch at the top of the pharynx; and the fibrous tumor, we call the naso-pharyngeal polypus, frequently has its growth there. It obstructs the posterior nares; and in bad cases, can be seen from the mouth. It is not of uniform size; is generally pear-shaped, and has a stem and a large body. Occasionally the growths are broad and cover the whole of the occipito-sphenoid bone.

These growths most often occur in young subjects, during the period of about fifteen or sixteen to twenty-four or twenty-five years of age. They grow very slowly, and the patient first suspecting that he has chronic catarrh, finally becomes aware of something which obstructs the breathing. The surgeon, if he fails to see anything in ordinary inspection of the throat, can detect the trouble usually by passing a silver catheter, or elastic catheter on a wire, carefully curved, and gently through the nares down into the throat on one side; it will soon be found that the catheter strikes a prominent obstruction on one side, or the other, and the location of the trouble can be made out. With the electric lamp in the throat and the rhinoscope the tumor can be seen back of the palate. If we have not this means, we can diagnose by means of the finger. The patient's mouth widely open and the finger passed in, up behind the soft palate; with this we can explore both of the posterior nares. It is a disagreeable experience for the patient, but does not produce any harm, and only the sensation of momentarily choking, and perhaps a little bleeding. In that way we can locate the growth; determine its size; shape; attachment; and see on which side of the posterior nares and pharynx it lies.

Being there and increasing, it may go on to cause a fatal result; leading to trouble at the base of the brain; to destructive changes in the pharynx; finally hanging down as low as the epiglottis and back into the œsophagus, in marked cases; and obstructing swallowing, and endangering the patient from choking while breathing or swallowing. It is then evident that it is very important, as soon as the diagnosis is made, that this growth should be removed; and a great many ingenious modes have been used to do it. The simplest form is to attempt to snare it by the snare passed through the nares, or else up behind the soft palate. If a lucky

case with good pedicle, this may sometimes be done. Nélaton found that the soft palate presented a barrier to the last one-half inch, which was in the way of getting the snare around. He devised the operation of splitting the soft palate, and passing a thread through either tip of the uvula; drawing it aside, and fastening it outside the mouth; and then you gain one-half inch or more of space by which you can get access to the posterior pharyngeal region. Then the polypus was removed by snare or forceps; and the soft palate was sewed up again.

It has been found, however, that most of the operations of this class, which merely snare off the polyp, do not prevent its subsequent re-formation; and that it is essential that the base should be reached and scraped away, and the periosteal layer under the mucous membrane, be scraped away, in order to insure against the recurrence; so that in order to get at this space other operations were devised. One was to cut a piece of bone out from the speno-maxillary fossa, turn the bone back, and expose the whole nasal cavity; this was Langenbeck's method.

Another was to saw across the top of the antrum, beneath the zygoma; split the palate process, after extracting one incisor tooth; depress and break down one superior maxillary bone; leaving it hinged on the pterygoid process; then pass the finger through this gap, push the septum to one side, and get ready access to the point you wish. That is the operation that I have done a number of times.

Whatever operation of this kind is done, after the polyp is scraped away and removed, the jaw is pushed back to place and wired, and the wound closes, and the bone unites, as a broken jaw does, and gives no subsequent trouble.

When it is borne in mind that before these operations were devised the only other alternative to destroy these large fibrous tumors was to excise the upper jaw, you see how much we have gained in the point of conservative surgery.

The prettiest operation of all was devised by M. Ollier of Lyons. You would not suppose at first it would give the needed room, but it does. It consists in sawing down and depressing the nose. You make a cut from the centre of the forehead, down each side of the nose, to the point where the artery goes to the ala. Cut through the periosteum to the bone on each side. Having made that cut, you take a moderately narrow and quite flexible saw, lay it as flat as possible on the forehead, and saw down through the nasal bone, down to the cartilage; upset the nose and drop it down on the lips. The nasal cavity is fully exposed. The vomer and septum are in the way. They are flexible and can be pressed over; and you have the means of reaching to the growth of the polyp, which the finger will exactly do; and thus you can extract large polypi by forceps, or by scissors, or by seizing them and tearing them out; and subsequently you go in and scrape this cavity. In these cases it is well always to operate in the upright position; and when any sign of choking comes on, bring the patient's mouth well forward and drop the jaw until they expectorate. Half etherization is the best. Thorough etherization during the incision through the skin and sawing the bone; the patient partially awake through the remaining stages. Although they make a noise, they remember nothing which has occurred; and it is much safer to have the patient sufficiently awake to retain a little control over

the epiglottis. Subsequently to this the nose is replaced. Two fine wire sutures are passed through the lower angle of the nasal bone, which hold the bone perfectly in place. These are brought out through the wound, and the wound nicely stitched. The wires must be left in two or three weeks; two weeks in the nose, and three in the jaw. The wires loosen and ulcerate; the bone decays a little around the holes, and, afterwards, untwisting them, they are drawn out with ease, and the sinus closes. Very little scar is left by this operation on the nose. There need be no fear that there will not be union. All the parts about the upper jaw and nose are so thoroughly supplied with vessels that they repair very great injuries, and always unite.

Malignant Forms of Growth in the Nose. — These are sometimes mistaken for the ordinary polypus. Soft cancerous growths occur on the mucous membrane of the septum low down, just inside the nasal cavity. The parts become obstructed and the patient thinks he has a polypus. On lifting the ala and looking at this growth, you find it is red and very vascular, with little tuberosities on it shaped like a strawberry, or raspberry. It bleeds on the slightest touch; occurs almost always in people of middle age; and it is essentially a soft and rapid growth of epithelioma.

This must be thoroughly removed. Usually it can be done by a very slight operation, by cutting around the ala and turning it up and then the septum and the growth may be cut away, the ala replaced and the only subsequent deformity is the little scar on the side of the ala. If that is not sufficient, excision of the structures inside, with portions of the jaw, must be done. It is not very common. I will call attention to the fact that polypus growing low down, in the elderly person, probably means cancerous growth. True polypi are never, I think, attached to the septum, but always to the turbinate bones. These malignant growths frequently start from the septum itself.

Abcess of the Septum. — Abcess of the septum is a very painful affection. You are familiar no doubt with what is called the little boil that forms within the tip of the nose. It is extremely painful, lasts five or six days, finally breaks and discharges inside the nose. It leaves no subsequent trouble.

There is another form which is more severe: abcess of the septum. It produces a curious deformity. It fills up the nostril completely, so that in seeing this patient first you would suppose the whole nose was filled with an enormous, red, malignant growth; but you find the duration of the disease is not more than a week, or ten days. The nose begins to swell; pain occurs; and this rapid ballooning out of the mucous membrane comes on, and the nostril is occluded. You find it is elastic to the touch.

The treatment is to make free incision and let out the pus, which is followed by speedy cure.

Making of a New Nose. — Artificial noses of *papier maché*, nicely colored and of a pattern to suit the taste of the wearer, are much better than any artificial nose made from the skin.

AN EPIDEMIC OF MUMPS. — An epidemic of mumps has recently occurred in an English village, in which 96 out of the 130 children in the village were taken ill. Many adults were also afflicted, but the number of patients was not so carefully recorded.

INFECTIOUS APPENDICITIS.¹

BY ROBERT T. MORRIS, M.D., OF NEW YORK.

GENTLEMEN:—There is only one way to prevent deaths from appendicitis, and that is to prevent deaths from appendicitis. Do you not know how? I do. So do you. Then let us cast the killick right here, and allow the restless, changing tides of argument to wash by as they will.

We have lost enough brothers and sisters and sons and daughters unnecessarily from appendicitis. Do not fail to remember the word "unnecessarily," when you long for the "touch of the vanished hand and the sound of the voice that is still."

For ten years we swarmed about the subject of appendicitis, trying first one hole and then another in a hunt for rules for guidance; but each was too small and we left the dead outside of every hole that was deserted. Now we are at the right place at last. There is only one rule for guidance. You know what it is. Those who do not accept it must lose a few cases that they did not really intend to lose, and they must let many trusting patients suffer tedious convalescence and inconvenient exacerbation at a time when they would prefer to be engaged in affairs. The troubled families will be satisfied when it is explained to them that these cases seem to be peculiar in their character.

I am prepared to admit that in many of the smaller towns it is not "policy" to remove an infected appendix at the very outset of appendicitis. At first I was shocked to hear physicians say that it was better to let a case of appendicitis run its course without operation, on the ground that the comments of rivals and of neighbors would ruin their practice if they attempted to do the right thing promptly. This expression of sentiment was so general, however, that I could not doubt its importance. O human nature, how polypragmatical art thou!

Even in the large cities there are still to be found most excellent authorities who are not yet ready to have the infected appendix removed as soon as it is discovered. This is because they are too busy to get out into the field and think at a mark, or because they have not had an opportunity to see the results of the inch-and-a-half incision and week-and-a-half confinement in appendicitis cases. They are men who are familiar with logic and who are accustomed to analysis and to rational deduction; but they work from the wrong set of data, and they give us a masterly impressionist picture of strawberries among autumn leaves.

The sweet-oil and opium jugglers detained us for a while. Did you see the Hindoo jugglers on the Midway? They put a man into a basket and then poked around in the basket with a stick, and explained to the audience that the man was not there. After a while the man came out of the basket again. The sweet-oil and opium jugglers tucked away an infected appendix and told us that infection was not there. After a while the infection stalked out again.

Every general practitioner in this audience has in his *climide* patients who are supposed to have recovered from appendicitis under medical treatment; and yet the answers that most of these patients would give to my questions would cause surprise. The bacterium *coli communis* and the pyogenic streptococci and staphylococci do not leave when we shoo them off

with poultices and opium and sweet-oil. They simply run and hide. I have removed a number of appendices in the presence of this class from patients who were believed by good authorities to be out of danger from relapses; and in all of the cases we have found destructive processes in progress. Sometimes the bacteria were slowly destroying the adenoid layer, which had swollen to the point of interference with its own vascular supply; sometimes proliferating eudarteritis was insidiously and surely laying the way for gangrene of the appendix; sometimes tuberculosis had become engrafted upon the weakened and diseased tissues; and in every case we found appendices which were malevolent in disposition.

Not long ago I quoted my statistics to an old practitioner who asked, with a sly twinkle in his eye, how many of the patients would have recovered without operation. "I do not know," said I, "but some of them would have died, and that settles it." Some of them would have spent more time in bed with every relapse than they did after the inch-and-a-half incision had been made; and that settles that question. I would rather remove infected appendices at a thousand dollars apiece from uncomplicated cases, and have all of the patients recover, than to add up small bills for visits to patients who died without operation, or who are left to go through the whole performance of another relapse of appendicitis after my so-called services have been rendered.

There are many cases of simple catarrhal appendicitis when we fail to look at the appendices; but when we look at them, they are infectious, exudative cases. If there is anything in a name, there is disaster in the name "catarrhal appendicitis."

They have charged me with being sensational. Let us see about that. Small-pox causes protracted suffering and death; but many patients recover from this disease, although the recovered ones are left with defects, as a rule. We know how to prevent deaths and defects from small-pox; and they are consequently unnecessary. Is there anything sensational about that statement? No! Now, please substitute the word "appendicitis" for the word "small-pox," and note the effect. It is the combination of fact and date that makes us listen *cum arrectis auribus*. Twenty years from now the facts about appendicitis will ring with a different timbre. Physicians who have not seen the pretty modern operation for prompt removal of the infected appendix are apt to draw in imagination a faulty view of the subject. They should interrupt the patient who is reading his morning newspaper in bed on the second day after the operation, and have a chat with him.

Now, look at the patient upon whom we are about to operate. He has an abdominal scar five inches long, and a ventral hernia. He has had one dangerous relapse of appendicitis since he was operated upon; and the insurance companies will not risk more than three or four postage stamps upon him. Four years ago he had an attack of appendicitis; and his physician in consultation with a surgeon waited for pus to form. Then the pus was evacuated, the appendix was left among adhesions, and the patient recovered. Recovered! Mockery! The surgeon who did the work bungled it by leaving it half done; and he is responsible for the ventral hernia and for the risk to life that resulted from leaving an infected appendix baited and set in the iliac fossa. I was the surgeon who gave

¹ A lecture at the New York Post-Graduate Medical School, December 30, 1898.

counsel and who did the work, at a time when there was excellent authority for doing it in that way. The family physician, like the other physicians upon whom I depend, would to-day be ashamed to call me to a case of appendicitis in which pus had formed.

This patient has given the usual history of slight exacerbation, of constipation and of little septic impressions since the time of his first acute attack. Three years ago he had a dangerous exacerbation, but was not where he could be operated upon.

The abdominal incision is now made; and I proceed to enucleate the appendix from a conglomerate mass of omentum, mesentery, colon, ileum, and adventitious tissue. The base of the appendix is ligated with fine eye silk, and the stump is buried with four Lembert sutures of catgut. On examination of the specimen, you observe that the muscular structure of the appendix is complete and hypertrophied. On inspection of the interior of the specimen, it is seen that the mucosa has disappeared and various tiny black or gray gangrenous spots are readily distinguished on the surface of the swollen and infiltrated adenoid layer.

We have had to learn three principal things in appendicitis within the past decade: (1) that appendicitis is very common, and that it simulates many kinds of abdominal disease; (2) that we must operate for removal of the appendix before pus has formed, if we would prevent deaths and hernia and uncomfortable complications; (3) that we do not need to make much of an incision, and that the operation is a neat and pretty one, instead of a thing to be dreaded in itself.

Original Articles.

NOTES ON PHOSPHATURIA.¹

BY PAUL THORNDIKE, M.D., BOSTON.

DURING the last three or four years the writer has had the care of a number of cases such as are often described and discussed in medical writings under the name of "phosphaturia." The perplexity which several of them caused him led to the collection of these notes from the meagre and unsatisfactory knowledge of the subject at our command; and it is the object of this paper merely to arrange these notes and present them to the Society in a way which it is hoped may prove of use.

Cases characterized by well-marked symptoms of digestive and nervous disturbance, perhaps also by neuralgic pains in the abdomen, back and loins, and associated with a more or less persistent phosphatic cloud in the urine, are the ones to which the writer refers. They are common enough to be familiar to us all, and are often severe enough to make serious inroads upon the patient's health. The patient comes to you complaining of a series of gastric symptoms: distress immediately after eating, heart-burn, eructations of gas, passage of flatus, constipation, and often of pretty severe colicky pain in the bowels. With these symptoms, more or less marked and pointing directly to fermentative changes going on in the stomach, are often associated extreme nervous irritability and sometimes indefinite but none the less annoying neuralgic pains in the back, loins and thighs. The urine is either

alkaline in reaction and turbid from the cloud of precipitated phosphates, or is neutral or slightly alkaline in reaction, clear in color, and becomes cloudy when even very slightly heated. If the trouble has persisted for any length of time, there is emaciation to a greater or less degree, and due of course to the ingestion of an insufficient quantity of food which is not properly taken care of after it reaches the stomach. Let us consider the urine of such a case for a moment, and the causes which may bring about such a state of affairs.

The phosphoric acid excreted in the urine is derived from the oxidation of the waste albuminoid tissues of the body, and also directly from the food. It is excreted by the kidneys at the rate of about three grammes daily, in combination with various bases, notably potassium, sodium, calcium and magnesium. Of these phosphates, those of potassium and sodium are very soluble and so are never deposited as precipitates in the urine; but the earthy phosphates (of calcium and magnesium) being soluble only in acid solutions, are often deposited from alkaline or neutral urines, and appear as a milky cloud in the urine. So it is at once apparent that this appearance of a phosphatic cloud in the urine has not of necessity anything whatever to do with the amount of phosphoric acid which is being excreted in the urine, and which can be estimated only by carefully quantitative analyses of the urine of a patient whose diet on successive days is carefully regulated; but it is merely an indication of a lack of acidity of the urine.

Now, when urine loses its acidity it does so (a) either from the formation of ammonia due to the decomposition of urea, that is to say, because the urine spoils after its secretion by the kidneys, and either somewhere in the genito-urinary tract (dependent upon some local lesion of the organs through which it passes or upon dirty instruments introduced into those organs) or in the air after it has been voided; (b) or it loses its acidity from the constant presence in it of too great a quantity of alkaline material which is not the result of any process of decomposition, but is a fixed alkali excreted in the urine chiefly in the form of carbonates of sodium and potassium. It is with these latter urines, those which are neutral or alkaline from the more or less constant presence of a fixed alkali, that we are concerned to-night. These persistently alkaline urines seem to be associated with a series of digestive and nervous symptoms which are of frequent occurrence and are of enough clinical importance to demand recognition as a distinct malady. It is as descriptive of this condition that the term phosphaturia is so often used. It would seem then that it is not the amount of phosphoric acid eliminated by the kidneys, but the diminished acidity of the urine and its associated symptoms, which are of interest in this class of cases. Many explanations for this lack of acidity have been offered us.

Bence Jones thought that when the contents of the stomach were most acid, for example, in certain disturbances of digestion, the urine was least so, the one counterbalancing the other. This explanation hardly suffices, as it is surely evident that in such conditions of the stomach, the excess of acid is not withdrawn from the tissues and so kept out of the urine, but is formed by the changes going on in the stomach.

Dr. Roberts thought the alkalinity was the result of the increased addition to the blood of alkaline bases from the food; but as the appetite in the condition is much more apt to be bad than good, and as there is no

¹ Read at the meeting of Boston Society for Medical Improvement, November 27, 1893.

evidence that food containing such alkaline bases is either eaten or absorbed in larger amounts than usual, this supposition does not seem of much value. What is true is that such urines contain a surplus of alkaline carbonates, as shown by analyses, and the alkalinity is most probably due to the constant and excessive elimination of these carbonates of potassium and sodium.

Ralfe says that this excessive elimination of carbonates may well be accounted for by three conditions:

(1) A general debility and its coincident feeble respiratory acts, leading to an accumulation of carbonic acid in the tissues. It is a noteworthy fact that in such conditions, for example, in patients convalescing from acute diseases, such urines are very frequently met with.

(2) A diminished secretion of bile, the frequent result of a duodenal catarrh produced by the irritation of the acid contents of the deranged stomach being poured into the duodenum. The bile being the chief secretion by which alkaline salts are excreted from the body, any diminution of its quantity gives rise to an accumulation of these carbonates in the blood, and therefore to a greater elimination of them by the kidneys.

(3) The acids formed by the fermentative changes which go on in the deranged stomach being of the fatty acid series, on entering the system are oxydized into carbonic acid and unite with the alkaline bases to form carbonates, which increase the alkalinity of the blood and of the urine.

That the excessive elimination of these carbonates and the consequent more or less persistent alkalinity of the urine may be explained entirely by such digestive troubles, is not probable, for there seem to be cases in which the phosphatic deposit is dependent solely upon nervous causes. In fact, cases of this sort are by no means uncommon. For example: Two or three years ago a middle-aged man living in Newfoundland, came to the writer complaining that for the last two years he had been suffering from frequent micturition and severe neuralgic pains in the abdomen and loins. He looked somewhat emaciated, and was nervous and depressed about himself and his personal affairs. There were no gastric symptoms, no venereal history, and a most careful examination revealed no lesion of the urethra or bladder. The urine was normal except for its lack of acidity and the almost constant presence of a phosphatic cloud. The man said that whenever he got into this nervous, worried condition, this same set of symptoms appeared. He was readily cured for the time being by a few hygienic suggestions, a tonic pill and some benzoate of soda. A second attack was brought on a year later by the excitement and worry he went through at the time of the great fire in St. Johns. The same treatment gave relief very quickly. This seems to be a purely nervous case, and such cases are common enough. The writer has seen several similar cases lasting often for months, in healthy but nervous men, after operations upon the penis and adjacent parts.

This deposit of phosphates has been studied by many eminent men, both clinicians and chemists, and has been found to occur in a great variety of diseases, for example, in acute brain diseases, acute mania, in pleuritis and pneumonias, in rheumatic fever towards the end of the attack, at certain periods of a typhoid fever, etc.; but the cases are rarely of much severity or duration, and practically take care of themselves, as

the general nervous and physical condition improves under proper care. That is to say, if the local cause be removed — be it digestive or nervous — the so-called phosphaturia disappears, as a rule; although sometimes it has existed long enough to leave behind it a mild degree of inflammation of the bladder or urethra, which may prove annoying enough to demand local or systemic treatment.

There are, however, many of these cases in which the condition persists for months or years; the urine gradually increases in amount and the patient's condition becomes really very serious, the general debility and nervous depression becoming extreme and the anæmia and emaciation marked. The general mental and physical condition of these patients seems sometimes quite beyond any help which the physician can offer, and the cases are most trying ones to care for. It is when we come to a study of this class of cases that we find the greatest confusion of belief in the minds of medical men. As the disease advances it often presents a clinical picture so similar to that commonly met with in cases usually described under the name "diabetes insipidus," that confusion both as to the terms descriptive of these conditions and of the conditions themselves is a most natural result.

"Cases characterized by increased thirst and excessive discharge of a watery urine of low specific gravity, free from sugar and albumen are grouped together under the general designation of 'diabetes insipidus'" (Roberts); and therefore these cases should properly be included under that definition. Other terms often used in describing similar cases, are polyuria, diuresis, polydipsia, hydruria. These terms are often carelessly used in medical writings, without much reference to the relationship which exists between the water and the solid constituents of the urines in question.

Some writers, however, — notably Willis (who was the pioneer in this direction), Tessier and Ralfe, — are much more careful in their use of terms, and have made many attempts at classifying cases characterized or accompanied by excessive excretion of urine, according to the relationship existing between the solid and fluid constituents. For example, Willis calls the cases of excessive amount of a watery urine deficient in solids — hydruria; those of excessive amount with the urea diminished, anasoturia; and again those of excessive amount with excess of urea, azoturia. Several other similar classifications have been made, and among them one by Dr. Tessier, of Lyons, who describes a series of cases resembling diabetes mellitus in the thirst, emaciation, increased amount of urine, neuralgic pains, etc., but the urine, instead of containing sugar, had the phosphates so largely increased in amount that the daily excretion was often as high as fifteen or twenty grammes, instead of in the neighborhood of three grammes, as it should be. To these cases Tessier gave the name "phosphatic diabetes." Ralfe reports other similar cases. So these writers make a distinct class of the cases which eliminate phosphoric acid in excess.

The excessive elimination of phosphoric acid is undoubtedly a factor in some cases of polyuria. That it is not present in all such cases is, I believe, definitely proven by many analyses. Then, before we can recognize a definite disease characterized by this phosphaturia, we must know in what cases of polyuria it occurs, and must try to know the explanation of its presence. We do not know these things. Our knowledge of the part which phosphorus plays in the

body, as well as our knowledge of its elimination in diseased conditions, is very small; although during the last twenty years good work has been done in this direction, both experimentally and clinically in Germany and England. Dr. Golding Bird associated some of his spinal cases, many of which were functional, with phosphaturia. Its presence has been noted in many cases of head-injury, in acute inflammations of the cerebral membranes, in acute attacks of mania, in anemia (and especially in its pernicious forms). It occurs in cases of diabetes mellitus; and sometimes the sugar will disappear from the urine in such cases, and be replaced by phosphoric acid. The explanation of this undoubted fact may perhaps be that the sugar in the tissues changes to lactic acid, which attacks bone tissue and dissolves out the earthy phosphates. This is Benecke's theory, I believe. Others have been suggested for an explanation of phosphaturia when sugar is not present in the urine; for example, an increased metamorphosis of nervous tissue, the irritation of some co-ordinating chemical centre, the influence of a disturbed condition of the nervous system upon the general bodily nutrition.

That these cases of polyuria accompanied by an excessive elimination of phosphoric acid have been carefully and accurately reported, is beyond question, and therefore their existence may be taken as proven; and they represent the only class of cases which is entitled to the name phosphaturia. But these cases are extremely rare, and when they do occur, present no well-marked clinical picture which will distinguish them from other similar cases of polyuria unaccompanied by an excess of phosphoric-acid elimination. Such a case, then, can only be recognized by careful quantitative analyses of the urine; and the term phosphaturia will have little interest for most of us in a clinical sense, as we may never encounter such a case in the practice of a life-time. All that we know of such cases is that they do rarely occur, that they are generally associated with grave physical disorder, and that they usually accompany nervous disturbances in which the blood and general nutrition of the patient are in bad condition.

Of the treatment of these stubborn cases there is but little to say. Annoying symptoms must be treated as they arise, and every effort made to better the general condition of the patient by careful hygienic and dietetic suggestions and suitable tonics. Alcohol always increases the flow of urine, and should be avoided. The administration of phosphorus or its compounds seems of little avail as far as experience has taught us, for as Ralfe says, "There appears to be no lack of these constituents in the system; the difficulty seems rather to lie in the want of power of the tissues to retain them."

To recapitulate the points which these notes attempt to emphasize; we have considered two conditions, both of which are commonly discussed under the name phosphaturia:

(1) The less important class of cases of digestive or nervous origin, in which the phosphatic cloud in the urine is merely an indication of a lack of acidity in the urine, which in its turn is usually traceable to some derangement of the stomach and duodenum or to some temporary nervous cause. These cases have no right to the name phosphaturia, are usually of comparatively short duration, and are cured by the treatment of the local cause and the consequent improvement of the general condition of the patient, which may closely

simulate the condition we commonly speak of as diabetes insipidus, and which should probably be classed as cases of this disease. The fact that some cases are associated with an increased elimination of phosphoric-acid in the urine does not at present furnish sufficient evidence to justify our making a definite clinical condition of it and calling it phosphaturia, phosphatic diabetes or anything else. The term phosphaturia, then, although perfectly proper in a chemical sense, as descriptive of a urine which habitually contains too much phosphoric acid, has in the writer's belief no clinical significance in so far as there is no well-marked set of symptoms constantly occurring as an accompaniment of this sort of urine.

(2) The rare cases of severe type and long duration which closely simulate the condition we commonly speak of as diabetes insipidus, and to which Tessier gave the name phosphatic diabetes, probably because the condition occurs occasionally in a case of true sugar diabetes. These cases are so very uncommon, and present such variable groups of symptoms when they do occur, that it seems scarcely worth while to give the name phosphaturia to any definite clinical condition, although, used as descriptive of these rare cases when the urine habitually contains too much phosphoric acid, the term phosphaturia is a perfectly proper one.

Before closing, a few words relative to phosphatic calculi seem appropriate. In many of the long-continued cases, the alkaline urine is often accompanied by a more or less persistent deposit of earthy phosphates for a period covering many months. This deposit may be very considerable in amount; and such patients usually bring to you samples of it which they have collected from the urinary sediment. Yet primary phosphatic concretions are by no means common; and such cases often recover completely, with no further bad result than a vesical irritability which the presence of the phosphatic deposit in the urine has created. This may perhaps be accounted for by the fact that the deposit is usually a fine, powdery precipitate, non-crystalline in structure, and with very little tendency to form masses or concretions of any size. Certain it is, that most phosphatic calculi, the so-called fusible calculi, are of secondary formation, made up of mixed phosphates.

NATIONAL REGISTRATION A NECESSITY.¹

BY SAMUEL W. ABBOTT, M.D., BOSTON.

In the present paper it is my design to state briefly some of the reasons for the adoption of a system of registration of vital statistics in each one of the United States—such a system as now exists in nearly every enlightened nation, the United States as a whole forming a marked exception.

Dr. Curtis, in a very intelligent discussion of the general subject of vital statistics, says: "A full and accurate knowledge of the people in every community is an indispensable requisite for the successful administration of public affairs. Such knowledge is obtained by the public authorities, from two distinct sources. In the first place, the enumeration of the people, by which the population, the numbers, the ages, the abodes, the professions, etc., of the individuals composing it are ascertained, is effected by the taking of a census. In the second place, 'the movement of the population,' under which term are comprehended the births, marriages and deaths occurring yearly, is determined by registration."²

Dr. Ogle states the objects of registration as follows: " (1) There are all the legal uses, where proof of death is required, such as the succession of property, payment of insurance monies after death, etc.; (2) there is the prevention of, or interference with murder, or foul play generally; (3) the provision of trustworthy data for the elaboration of statistics concerning health, disease and mortality."

The purposes of registration are manifold, and their importance emphasizes the necessity of having this department of statistical work conducted in the most thorough and intelligent manner.

It serves in the first place to facilitate the identification of individuals for the transmission of property and for the protection of life against crime.

Second, it affords data for the determination of life contingencies, which form the basis of life insurance. Sufficient importance has never been given to this use of the statistics of mortality in this country. The figures upon which this very great and important business (amounting to many millions in each year and affording protection reckoned even by billions) is founded, can only be obtained in this country from a very small portion of the people, having registration extending over a long period of years.

But, third, and most important of all, it furnishes to sanitary science, and to the medical profession in general, most valuable information regarding the public health.

With these facts in view it is a sad comment upon the civilization of a great nation, that sixty-five millions of people are to-day entirely without any general system of registration of vital statistics; that the birth-rate, the death-rate and the marriage-rate of this country as a whole, are absolutely unknown.

There is no information to be had, for example, as to the birth-rate or the death-rate of this great State of Illinois, within whose limits we are assembled, the third State of the Union in its population of more than four millions. We have absolutely no means of comparing the death-rate of Chicago with that of the

rural population of the remainder of the State; since, while the former is known with some degree of certainty, the latter is unknown. There is no means of comparing the death-rates of any of the counties of the State (or of larger districts) with each other.

Of the foreign countries, most of the largest and enlightened nations of Europe have had registration of a more or less complete character for periods varying from a quarter to a half century or more. It is a matter of great importance in the study of nations that their conditions and circumstances may be compared with each other. But in this very important direction we, as a nation, have no possible means for making such a comparison. When individual States are considered, we find a little improvement. States embracing about twelve per cent. of the population of the whole country have fairly complete systems of registration; while other States, having about as many more inhabitants, have enacted adequate laws, but thus far the execution of these laws is not fully carried out.

What then is needed to introduce and perfect a thorough system of registration throughout the whole country from Maine to Oregon, and from the Gulf to the Great Lakes?

(1) The enactment of laws in every State providing for the registration of births, marriages and deaths. The more uniform such laws can be made with reference to the information to be obtained in individual certificates, the better.

(2) The cordial co-operation of the general government in providing a central authority for the collection and publication of the statistical material of the individual States. Possibly grants might be made to the younger States to facilitate the introduction of this very important work.

(3) The necessity of awakening the interest of the medical profession in this work and the need of their hearty co-operation in aiding it in every possible manner is apparent. To this end the raising of the standard of medical education will have a favorable effect. The teaching of vital statistics, as an essential part of medical and especially of sanitary education, should be urged.

(4) The placing of the work of registration in the hands of trained medical men, who should act as registrars. These should not only be medical men, but also men who are experts in the subject of vital statistics at least. This principle is recognized by all the foremost authorities in public hygiene. No one doubts for a moment the wisdom of the British government in entrusting the registration of England to such men as Dr. Farr and Dr. Ogle. And the same may also be said of the French and German governments. Due authority should be given to the registrars of States and of municipalities to examine the returns of death, carefully, and to institute inquiries in all doubtful cases, especially when the certificates are signed by unqualified practitioners.

(5) In addition to the foregoing considerations, a revision of the nomenclature and classification of diseases is demanded, which shall be in harmony with the progress of medical science. Such revision, whenever it shall be made, should be uniform throughout all countries having registration, in order to facilitate the international comparison of the results obtained by registration.⁴

While the accurate registration of all deaths em-

¹ A paper read at the World's Congress of Hygiene, at Chicago, October 12, 1893.

⁴ See Transactions of the Massachusetts Medical Society, 1892.

braced under the five general divisions or classes of disease is desirable, there is one class which has a peculiar interest to the sanitarian, and that is the group of infectious diseases, or those to which for a half-century the name "zymotic" has been applied. The diseases of this class, or at least a majority of them, are undoubtedly amenable to those preventive measures which constitute a large share of the work of sanitary authorities. Hence all such authorities must necessarily recognize the great importance of having a definite knowledge as to the mortality from infectious diseases from month to month, and from year to year. Such knowledge can only be had under a careful system of registration thoroughly carried out. To this class of diseases belong typhoid fever and phthisis,² diseases which destroy life during its most productive period, and hence involve a great economic loss to the population. The steady decline in the mortality from these diseases in cities and towns having such municipal sanitation as is required, is too well recognized to require lengthy comment here. But without a good system of registration the question of improvement or of retrogression could not be known with any degree of certainty.

Legislatures are slow to act when definite, tangible evidence or statements as to the actual results accomplished by sanitation are not to be had. Hence the importance of establishing such thorough and complete systems of registration as shall furnish the desired information.

The relation of the vital statistics of any community to the public-health administration of that community is very much like the relation which the counting-house of any commercial firm bears to its business. The business may be great or small; it may conduct commercial transactions over a very large extent of territory; it may own property, factories or mills in different manufacturing towns; it may employ large or small numbers of workmen; but, if it is desirable to obtain any definite information as to the extent or character of its operations, their success or failure, one must go to the counting-house or the business-office, where he can obtain full and accurate knowledge of the standing of the firm, of the amount of its business, and of its plans and methods. The assets and liabilities of the firm are here matters of record; and its journal and ledger, its daily, weekly, monthly and yearly balance-sheets tell us of the actual condition of its business.

Applying this illustration to the operations of a sanitary authority, the vital statistics of any community tell us its actual progress or retrogression in the excess of births over deaths, or, *vice versa*, of deaths over births. The changes, too, in the death-rates from preventable diseases both individually and collectively are instructive, as showing to a certain extent the results of thorough and efficient sanitary work. They constitute the sanitary barometer by which not only present conditions are known, but also with some degree of certainty, future conditions may be foretold.

Let the following facts serve as an illustration:

Upon a comparatively large river in my own State are some half-dozen manufacturing cities and towns. Let these cities and towns be represented as follows: A, the cities and small towns upon the upper portion of the stream (embracing 300,000 inhabitants); B and

C, two larger cities upon the lower portion of the same stream; D, a smaller city near its mouth. The entire population upon the water-shed of this river is about a half-million inhabitants.

The State Board of Health collects information weekly from the cities and towns within the limits of the State, as to the mortality from infectious diseases, including the cities and towns upon this river. It is also authorized by law to examine all the water-supplies of the State, a work in which it is continually engaged. The statutes forbid that streams used as water-supplies shall be used for the discharge of sewage; but the river in question is exempted by law from the operation of this statute, and sewage goes into it without hindrance from A, B, C and D. Now B and C take the water of this river directly and without filtration for domestic use. Sewage from A enters the water-supply of B; sewage from A and B enters the water-supply of C. As might be expected under this condition of affairs, typhoid fever has become more than epidemic at B and C, the mortality from this cause bearing the following ratios for the twenty years (1871 to 1890): The typhoid death-rate of the State being taken as 100, that of B was 155, and that of C was 170, while in the last five years of this period the excess rate was still greater. Any slight prevalence of typhoid fever in the sewered portions of cities and towns included in A was pretty sure to be followed by a greatly increased prevalence in B and C.

Up to the fall of 1892 the water-supply of the small city D was not taken from the river, but from a spring upon its shore. During the dry season of 1892 this spring became inadequate, and the water-supply which was furnished by a private company was increased by extending a water pipe to the river and supplementing the supply directly from that source. In the frequent routine examinations of the water-supplies conducted by the State Board of Health, this fact became known to the board, in consequence of the immediate change in the quality of the water as shown by its analysis. Under these circumstances the board immediately warned the water company of the danger of using water from a constantly polluted stream into which the sewage of a population of several hundred thousand was discharged. The company took no notice of this communication, but continued pumping water from the river and distributing it to the inhabitants. What was the result? In less than two months an epidemic of typhoid fever attacked the population using this water, more severe in character than had been known in that city for a half-century. It so happened that this event occurred during or at the beginning of the session of the State legislature. The citizens were soon aroused to a sense of the danger of the situation. The mayor appealed to the legislature for such aid as proper legislation might afford; and while the franchises of water companies have usually been guarded with jealous care, in this instance the flagrant disregard of the admonition which had been given them and the consequent sickness and death of many citizens, which might have been avoided, had they not neglected the advice of an experienced authority which had thoroughly examined the whole situation, induced the legislature to give to the city the right to introduce an independent supply, and at the time of this writing (October, 1893) the city has, by an overwhelming majority, voted to take this action.

I have presented this illustration, not so much for

² By almost universal consent, phthisis should be included in the category of infectious diseases.

the purpose of showing what might have been done in preventing sickness and loss of human life under circumstances of careful observation, followed by advice to a responsible corporation and an obedient following of such advice, but for the purpose of showing the usefulness of a careful system of vital statistics, embracing a weekly return from the cities and towns along the banks of this river, of the deaths and causes of death, by which a warning reaches the State Board of Health and may be by it transmitted to the local boards, of the existence of unusual prevalence of epidemic disease.

About a quarter of a century ago the death-rate of England was constantly higher than it is at the present day. It was noticed that this high death-rate was mainly in the large towns and cities. Sanitary works were introduced in these cities, embracing new water-supplies, systems of sewerage and disposal of refuse, etc., and very soon the death-rate was diminished in nearly every city in which such improvements had been introduced.*

Now the point which I desire to enforce, is not so much the fact of such improvement as a natural consequence of thorough sanitation, but the method by which this fact was ascertained. The foundation or basis upon which the general public movement for these improvements rested, and which justified their introduction, was the death-rate of the cities in question. The computation of this death-rate and the comparison of the mortality before and after the introduction of public sanitary improvements was made possible only by the existence throughout the whole country of a complete and accurate system of registration.

Again the possibility of conducting such valuable and instructive investigations as are presented in Dr. Longstaff's "Studies in Statistics," and in the older papers of Buchan and Mitchell, is only made certain by the existence of a system of registration.

In this connection I desire to call your attention to one class of causes of death which is more or less preventable, although not in the same sense and degree as the group of infectious diseases; I mean the class of deaths by violence. All measures which tend to ameliorate the condition of man, to lessen suffering, poverty and intemperance, to protect life and to make it more secure from danger, will thereby diminish the annual mortality from homicide, suicide and accident. In the State of Massachusetts, by a statute of 1885 the registration of this class of deaths was made much more thorough and complete than it had previously been. At a still earlier date (1877) the coroner system had been abolished as a useless relic of antiquity, and an entirely new method of inquiry was introduced, which was modelled after the better modes in operation in continental Europe.

The new plan of procedure provides for the separation of the medical from the legal duties connected with the investigation of deaths by violence, the former being entrusted to a corps of well-trained medical examiners, while the latter are performed by the district judges. The operation of this system for a period of fifteen years has been entirely satisfactory. It is at once more economical and far more efficient than the coroner system which it superseded, and no one at the present day desires to return to the old method.

I would therefore commend this mode of investigation, together with the improved system of registration

which now constitutes a part of the general plan, as suited to the wants of any community comprising either a large or a small population.

To conclude, a thorough system of registration is not only a valuable auxiliary, but is a natural and essential department of the work of any general sanitary authority; and in every State where no provision is made for the collection, tabulation, and publication of the vital statistics of the population, measures should be taken with the least possible delay for the carrying out of this important public duty.

Clinical Department.

TWO CASES OF HYDRAMNION ASSOCIATED WITH ABDOMINAL DISTENTION IN THE FÆTUS.¹

BY CHARLES W. TOWNSEND, M.D.

CASES of true hydramnion, where the distention is so great as to cause morbid symptoms and the premature expulsion of the fœtus, are comparatively rare. The causes of hydramnion are many; but one of the most common is stated to be a morbid condition of the fœtus resulting in mechanical disturbances of the placental or umbilical circulation. Barton Cooke-Hirst, in "The American System of Obstetrics," says: "That increased internal pressure within the umbilical vein will give rise to a transudation through the amnion, has been abundantly proved by Sallinger. . . . It may be generally stated, therefore, that any condition of the fœtus that will raise the blood-pressure in the umbilical vein, thus increasing the blood-pressure in the placenta, may give rise to hydramnion." The two cases of hydramnion I am about to relate appear to belong to this class. Hirst instances, among other morbid changes in the fœtus, cirrhotic livers, and tumors which obstruct the umbilical circulation.

The maternal histories in my cases are very much alike. Both were patients of the Lying-in Hospital; both were uncomfortably distended at the seventh and eighth month, so as to be as large or larger than at full term; and both gave birth prematurely (one at seven and one-half months, the other at eight months). A description of the labor of one of these cases will do for both.

Mrs. S., a primipara in the out-patient department, seven and one-half months pregnant, was seen November 20, 1887. The abdomen was very large, and tense as a drum. On external palpation no fœtal parts could be felt. The fœtal heart was heard faintly. By vaginal examination the fœtal head was felt above the brim, and ballottement could very easily be obtained. When the membranes were ruptured a large quantity of water came away, and the rush of water was so great after the birth of the child, which speedily followed, that it flooded the bed down to the foot, pouring over the edge and flowing along the floor. The labor previous to this had been a tedious one, lasting thirty-two hours. The child lived only forty-five minutes.

In the second case the mother was a multipara. Here the child lived nearly an hour. Both the infants were females, the sex which largely preponderates in cases of hydramnion. The mothers in both cases made good recoveries. In both babies the abdomen was much distended, causing in the second case a delay

* Ninth Report of the Privy Council, England.

¹ Read before the Obstetrical Society of Boston, November 11, 1888.

in the extraction of the body. I obtained an autopsy in each case.

CASE I. Autopsy of seven and one-half months' female foetus, weight three pounds. Circumference of head, eleven inches; of chest, nine and one-quarter inches; of abdomen, eleven inches. Abdomen much distended, the skin tense and shining. Abdominal cavity contained a drachm of clear serum. Liver much enlarged, extending below the level of the umbilicus on the right side and as far as the umbilicus in the median line; much distended with blood. Other organs normal.

CASE II. Autopsy of eight months' female foetus, weight nine and one-half pounds. Circumference of head, thirteen and one-quarter inches; of chest, fourteen inches; of abdomen, seventeen and one-half inches. The abdomen was very much distended with fluid—a fact which accounted for the weight of the child—its superficial veins being prominent, as may be seen by the accompanying photograph. On open-

ing the abdomen considerable clear fluid flowed out, and there were found to be numerous adhesions among the abdominal viscera. The liver and spleen were normal. The fluid was not, however, the cause of all the distention, for a large sac was found full of fluid extending up out of the pelvis as high as the umbilicus. On closer examination this proved to be the vagina, much distended with urine, the uterus being borne on the summit of this large sac. I was unable to discover with a fine probe any external meatus or opening to the vagina, and it seemed probable that the bladder emptied into an occluded vagina. The bladder itself was slightly enlarged, but being more muscular than the vagina was able to resist the pressure of urine, while the vagina gave way. Dr. Whitney, to whom I showed the specimen, suggested this explanation.

The association of abnormal foetal abdomens in these two cases of hydramnion would seem to be more than accidental. It is probable in each case that there was increased pressure in the umbilical vein with the resulting hydramnion.

A CASE OF PUERPERAL SEPTICÆMIA.¹

BY GEORGE HAVEN, M.D.

THE following case of puerperal septicæmia is, I think, sufficiently interesting from a bacteriological standpoint to justify the time which I shall occupy in reporting it to this Society.

The patient was delivered at the Boston Lying-in Hospital. Dr. J. L. Morse has made cultures from

¹ Read before the Obstetrical Society of Boston, November 11, 1893.

the patches which were found in the vagina and on the cervix, and will speak of the result of his research after I have reported the case.

R. W., dissipated history, entered the hospital August 29, 1893, in labor, membranes ruptured. She had been examined before entrance by some unknown person. She was delivered after a very long second stage by high forceps and axis traction. Twelve hours after delivery she had a chill, and the temperature went up to 104°.

August 31st. Lochia was very foul. Dr. C. W. Townsend, in whose service the case was delivered, found the vagina covered with whitish-yellow deposits, which could not be scraped off. The uterus was washed out with corrosive and carbolic. The pulse was weak and rapid; pain and tenderness were present over the uterine area. Epsom salts were given until she had free movements. She also had brandy and egg-nogs.

I examined her on September 1st, when my turn of service began at the hospital. Condition about the same as at last examination. Dr. Morse removed sufficient of the membrane to make cultures. The uterus was washed out with corrosive and peroxide of hydrogen. An iodoform pencil was introduced into the cavity of the organ, and iodoform powder dusted into the vagina. She had at this time a diarrhoea, probably septic. Nourishment was pressed as much as possible. She was given champagne in place of brandy, as the former nauseated her.

September 2d, she was feeling slightly better. Her condition remained about the same up to the 9th of September, when she complained of pain over the uterus. A flaxseed poultice gave her some relief. There was a slight trace of albumen in the urine, also a few hyaline casts.

September 25th, she was much better.

September 27th, she had a very severe headache, which did not yield to treatment, and made me think there was a distinct renal element in the case. She was given digitalis and acetate of potash. The urine contained a large trace of albumin, as well as many granular and hyaline casts.

On September 28th she had a convulsion, and was comatose after it. She was given croton oil and a hot-air bath. A movement occurred about midnight, but the skin remained perfectly dry; and she died at 5.40 A. M., September 29th.

This was a case where, if the kidneys had remained normal, recovery would have been possible. As it was, she died of uræmia. The kidney lesion may possibly have been secondary to the septicæmia, but was probably present when she entered the hospital. The rapid and violent development of her septicæmia (twelve hours) makes it almost certain that she was septic when admitted.

BACTERIOLOGICAL CULTURES FROM A CASE OF PUERPERAL SEPTICÆMIA.¹

BY J. L. MORSE, M.D.

BEFORE the employment of cultural methods for isolating micro-organisms, various observers found chains of micrococci in the tissues of women dead of puerperal fever. Mayrhofer, in 1865, was the first to publish such an observation, and was rapidly followed by

¹ Read before the Obstetrical Society of Boston, November 11, 1893.

others, among whom may be mentioned Rindfleisch, Recklinghausen, Klebs, Orth and Doléris.

Pasteur, in 1880, was the first to cultivate the streptococcus from the organs of women dead of puerperal fever. Similar results were obtained by Fränkel, Bumm, Winter and many others, so that at present there can be no doubt that the streptococcus pyogenes stands in a causal relation to a very large proportion of the fatal cases of puerperal disease. Widal found streptococci in nearly every case in which he performed an autopsy, and also demonstrated that the most divergent forms of puerperal affection, for example, endometritis, peritonitis, pyæmia and even phlegmasia alba dolens, could be traced to streptococcus infection.

Streptococci are not the sole cause, however, for organisms that lead to wound-infection elsewhere can also give rise to puerperal wound-infection. Brieger was the first to show that the staphylococcus could cause fatal puerperal fever, and his statements were soon verified. They, however, rarely cause the more severe forms, but are often combined with streptococci.

Krönig¹ has recently demonstrated that gonococci may occasionally be the cause of some of the milder cases of puerperal disease.

Von Franque,² in a recent article, reports a case of moderate severity, in which he found a pure culture of the colon bacillus in the uterus, unaccompanied by any other organism. A pure culture from this case readily killed guinea-pigs and rabbits. As far as I know, this is the first and only reported case of puerperal infection due to this bacillus. It is not to be surprised at, however, when we consider the proximity of the rectum and the frequency with which the colon bacillus is found in purulent affections of the abdomen, especially appendicitis.

It is probable that other organisms may cause the trouble, either alone or in combination, notably the bacillus proteus.

In the case in question a sterile swab was introduced into the interior of the uterus and another into the upper vagina under aseptic precautions. Cultures of both were made on Löffler's blood-serum mixture, and showed a pure growth of a short bacillus. Agar plates were made from each of these tubes, and showed a pure culture of colonies resembling in their growth the colon bacillus. This bacillus, when cultivated on the various media, corresponded in every way to the bacillus coli communis, that is, grew on nutrient gelatine without liquefaction and with the formation of a few gas-bubbles; formed gas in sugar agar, acidified and coagulated litmus milk; showed a profuse, moist, yellowish growth on potato; was motile in hanging drop of bouillon culture; and gave the indol reaction in Dunham's solution.

A NOTE ON THE USE OF ICHTHYOL.¹

BY A. D. SINCLAIR, M.D.

I WISH to say a few words about the drug ichthyol, which has come to rather extensive use of late, especially in Germany, but not used as yet to any great extent in this country. Some observations, however, published from time to time in the journals, have

given a favorable impression of its value in the treatment of various conditions of the system, local and constitutional.

Ichthyol is an exudation from strata of rocks in the Jura, which abound in fossil fishes. It is of a tarry consistency. Less than a dozen years ago this substance was brought to the notice of chemists in Hamburg, I think, who analyzed it. At all events, Professor Unna, the famous dermatologist of that city, was the first who brought it to the knowledge of the medical profession by the report of cases of certain cutaneous affections successfully treated by its use. This exposition led to further elaboration of the substance by the chemists, Cordes, Hermanin & Co., of Hamburg, who have made a variety of combinations of the original product with ammonium, sodium and zincum, each of which is supposed to possess — and some to my certain knowledge have — distinct influence therapeutically. Pills and capsules of the same are also made by them, and are beautiful specimens of pharmaceutical art. The liquid preparations of ichthyol exhale a strong sulphide-of-ammonium odor, which, however, soon passes off on exposure, and need not be, as some have written, prejudicial to its use as a drug to be used in one's consulting-room.

I shall now give in a few words my own experience of the use of ichthyol since I first had it brought to my notice in March, 1891, and will anticipate by stating that its most characteristic effects, when applied locally in certain affections of the pelvic viscera, are *anodyne and astringent*.

I have had many opportunities to test the value of ichthyol in congested states of the pelvic organs of women with various dilutions of the above-named preparations, but have arrived at a point where I think I find the best result from a fifty-per-cent. with glycerine. This strength of the drug has been used by me in numerous cases of recent and chronic congestions of the reproductive organs, as well as those of the vagina, urethra and rectum.

In prescribing ichthyol, the druggist will always dispense the sulpho-ichthyolate of ammonium, as this is the most known preparation. The combination with sodium I have not tested, but that with zinc is remarkably astringent, and its effects in certain conditions, to be arrived at by experience in the use of this medication, are a little surprising. I have not had a single bad effect in the use of preparations of ichthyol, although I have applied them many hundreds of times. I therefore, from my experience of their effects in certain conditions in the practice of minor gynecology, would recommend a trial to those who have never used them, and a more extended application by those who have already tried them.

I have in these short remarks confined myself to the use of ichthyol in congestive and chronic inflammatory states of the pelvic organs, but could say something favorable of it in the treatment of dyspepsia, chronic diarrhoea and erysipelas.

THE EFFECTS OF MEDICAL LEGISLATION. — At the last meeting of the State Board of Medical Examiners of the State of Washington, held in Seattle, there were twenty-two applicants for a license to practise, of whom twelve failed to pass the required examination and were rejected. The Board now requires a general average of 75 per cent. on all branches. — *Medical News*.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR Meeting, November 11, 1893, the President, DR. CHARLES M. GREEN, in the chair.
DR. GEORGE HAVEN reported

A CASE OF PUERPERAL SEPTICÆMIA.¹

DR. J. L. MORSE showed
BACTERIOLOGICAL CULTURES FROM THE ABOVE CASE.²

DR. EDWARD REYNOLDS said that he saw the case reported by Dr. Haven on the fifth day, for the first time, and was impressed with the fact that it was different from most cases of puerperal septicæmia.

DR. J. G. BLAKE thought that the great rapidity in the spread of the pseudo-membrane was very interesting.

DR. C. W. TOWNSEND said that he was astonished, on first examining the case, about twenty-four hours after labor, to find the whole vagina from the cervix to the vulva covered with an extensive pseudo-membrane. He had no doubt but that the patient, who had been leading a dissipated life, and who was unable to give a clear account of herself, had been in some way infected before entrance to the hospital.

DR. G. HAVEN said that the patient had recovered from the septicæmia, but died of renal disease. Whether this was induced by the sepsis he was unable to say.

DR. C. M. GREEN said that a number of septic cases at the Boston City Hospital have nephritis, although this lesion is also sometimes entirely absent.

DR. J. L. MORSE suggested that this nephritis, in septicæmia, was similar to the nephritis in scarlet fever. The only other case of puerperal septicæmia in which the colon bacillus was present, recovered.

DR. C. W. TOWNSEND reported

TWO CASES OF HYDRAMNION ASSOCIATED WITH ABDOMINAL DISTENTION IN THE FŒTUS.³

DR. J. G. BLAKE mentioned a case of enormous distention coming on suddenly. Notwithstanding this, the patient went on to full term, and gave birth (together with a great flood of water) to a living child.

DR. A. D. SINCLAIR had had a case of extreme hydramnion where the child was anencephalic, and he asked whether, in these cases, hydramnion was apt to occur.

DR. E. J. FORSTER had had but one case of anencephalus without hydramnion.

DR. EDWARD REYNOLDS had seen two cases without hydramnion.

DR. C. M. GREEN had seen one case without it, and he did not think there was any necessary connection between the two. Anything that interfered with the umbilical circulation, whether by disease of the liver or abdominal tumors of the fœtus, as in Dr. Townsend's cases, or by twisting or knotting of the cord, might cause hydramnion. The cause is sometimes to be found in disease of the placenta or decidual tissues. Oftentimes, however, it is difficult or impossible to find

a cause. These points he had brought out in a paper on hydramnion read to the Society some ten years ago.

DR. TOWNSEND, in closing, said that it was difficult to draw an exact line between hydramnion and an amount of liquor increased within normal limit. Cases of true hydramnion, however, rarely went to full term on account of the extreme distention, and often gave rise to morbid symptoms. In both of his cases the association of abdominal distention in the fœtus, which might result in interference in the placental circulation, suggested strongly the origin of the hydramnion.

DR. A. D. SINCLAIR read

A NOTE ON THE USE OF ICHTHYOL.⁴

DR. J. G. BLAKE had recently used ichthyol, and considered it a valuable drug. In the vaginal pruritis of pregnancy he had used it with great relief, combined with lanolin; and he found it much better than strong solutions of cocaine. In the case he mentioned the mucous membrane of the vagina was very raw and painful. Carbolic acid, previously used in this case, had failed. One objection to ichthyol is its odor.

DR. SINCLAIR spoke of its use in the pruritis of diabetes. The form usually dispensed is the sulpho-ichthiolate of ammonium, and it is generally diluted fifty per cent. with glycerine. The zinc compound is much more astringent.

A RARE FORM OF THE HYMEN.

DR. F. W. DRAPER reported an instance of abnormally-formed hymen which had recently come under his observation. The subject of the anomaly was an unmarried woman, twenty-five years old. The hymen presented the following characteristics: From the middle point of the free edge of a moderately thick, crescentic, membranous curtain at the posterior segment of the ostium vaginae there projected forward and upwards a thin band or bridge about one-sixteenth of an inch in diameter, composed of tissue that was quite elastic and not tense, and having its anterior insertion just below the meatus urinarius. This band divided the vaginal outlet into two symmetrical orifices, oval in shape, each of a size to admit the tip of the index finger. The vaginal canal, above this unusual curtain at its entrance, was entirely normal.

Dr. Draper remarked that the possessor of this peculiar arrangement of the hymen could offer it as very strong presumptive evidence of her chastity and virginity.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, November 13, 1893, the President, DR. C. F. FOLSOM, in the chair.

REMOVAL OF FOREIGN BODY FROM THE ANTERIOR CHAMBER OF THE EYE.

DR. G. HAY: I wish to speak briefly of a case of foreign body in the anterior chamber of the eye, which I removed recently with a magnet. The foreign body did not project from the cornea. It had passed into the anterior chamber, but the anterior extremity was lodged in the cornea, and just appeared on a level with the outer surface of the cornea: possibly it pro-

¹ See page 140 of the Journal.

² See page 140 of the Journal.

³ See page 139 of the Journal.

⁴ See page 141 of the Journal.

ided slightly, but not enough to grasp it with forceps. The foreign body was a very narrow piece of iron, the end of a needle, about one-tenth of an inch long. The inner end touched the iris, and it had been in the eye about two weeks when the man came to me. The history was that, while he was hammering, something struck the eye. Some one in the room remarked that there was blood in the eye. I suppose that the iris must have been wounded. When I saw him the blood had disappeared, and you saw this foreign body, the end of which was on a level with the outer surface of the cornea. I knew that an attempt to remove it by the point of the narrow knife would be dangerous, since one is liable to push the foreign body in, and might be obliged to do iridectomy, and might even then not be able to get the foreign body. While I was thinking how to remove it the man said: "Don't they sometimes use a magnet?" I had a magnet, which I prepared and carefully applied. At first it produced not the slightest result. The cornea was so tightly around the iron that it produced no effect. After two or three attempts, it occurred to me to cut with a very sharp-pointed knife where the bit of iron showed itself, in order to loosen it. I cut as carefully as I could on two opposite sides of the iron, and in so doing I noticed that the anterior chamber began to leak. This is what would be expected if I had attempted to pry it out; I should have opened the anterior chamber. It occurred to me that there would now be a better chance of pulling it out. I applied the magnet again, and it came out very readily.

The case did perfectly well. It is not a new case at all, and is only interesting on account of the way in which the piece of iron came out, and as an instance of a comparatively new method of treating an accident which formerly might have resulted disastrously.

DR. M. H. RICHARDSON showed a

LARGE DIFFUSE FIBROMA OF THE BREAST, WITH SPOT OF MEDULLARY CARCINOMA.

This specimen is interesting from the fact that it shows a cancerous degeneration in a large fibroma of the breast. I have frequently advised patients with a simple fibroma of the breast not to have any operation performed; that the tumor is not dangerous; that it simply interferes with the comfort of the patient from its size. I have never before seen a benign tumor of the breast which has taken on malignancy. In several cases of intracanalicular fibromata there have been suspicious spots found somewhere in the disease. This is the first case of its kind where there has been a marked malignancy both in gross appearances and history, and in the microscopic examination.

The patient, a woman of thirty-four, single, is a stitcher in a shoe-shop. In her work the shoe is brought constantly against the upper part of the breast. Her attention was called to the breast for the first time last June. She felt a hardness there. There was no family tendency to cancer. She has always been well and strong. I found a large tumor occupying the whole left breast. In the lower and anterior quadrant the skin was distinctly infiltrated. The axilla contained several large glands. There was no evidence of internal metastasis. It was impossible to remove the breast without sacrificing all the skin over it. I took, in addition to the skin over the breast, a circular margin of about an inch in all directions. This method

left an enormous wound to be filled by granulations. Without cutting away the breast, I carried the dissection along the edge of the pectoralis major and the anterior axillary border until the last of the glands had been dissected out. The breast and axilla, therefore, came away in one continuous mass. The operation was performed on Saturday—the day before yesterday—and thus far the patient is making very good progress.

It is always desirable in these operations to take a broad margin of skin. Recurrences in the scar always seem to me an evidence that not enough has been taken. The error in removing breasts generally consists in trying to shave the tumor too closely in order to get a first intention. The most important thing is to get the disease out, then we should, for the first time, think how we are going to close the wound.

EXCISION OF THE ELBOW-JOINT.

Dr. Richardson also described a case of chronic rheumatic arthritis of the left elbow, with excision of the joint, which was shown. The patient, a woman of forty-seven, had, seven years ago, pain in the right shoulder, supposed to be rheumatic. About five years ago the left arm began to trouble her. Six years ago she had some rheumatic trouble in the feet. There is no consumption in the family at all except one aunt. The pain has been so great in the left elbow during the last six years that she has been disabled most of the time. Finally, it was put up in plaster-of-Paris by the attending physician Dr. McColester, of Waltham. The immobility resulted in some alleviation of pain, but not complete. Meantime the left elbow has become more or less ankylosed. On careful examination there was undue prominence on each side of the olecranon. This soft swelling did not seem to be tender. Movements of the elbow were extremely painful, especially extension. I have had this case under observation since the 10th of May of the present year. During this time there has been no improvement whatever in the subjective signs. The elbow has been almost entirely disabled and there has been a great deal of pain. After very careful deliberation I decided to try forcible extension to the movements of the joint. Five or six days ago, under ether, I broke up the adhesions and extended and flexed the elbow, and at the same time rotated the forearm. This was followed by a great deal of pain. Dr. Warren saw this case in consultation during the anesthesia, and we both thought that there was probably a tubercular element in the disease. Whether tubercular or not, it seemed best to excise the joint, not only to relieve the pain, but to give a more useful joint than the one she had. The bones were excised on Saturday in the usual manner. I did not use any efforts at hæmostasis. I did not use the Esmarch bandage or tourniquet. It seems to me better to stop the hæmorrhage as we go in operations of this kind, because we thereby avoid in the best manner subsequent oozing and extension of flaps. Patient to-day is sitting up, and there is no pain.

Excision of the elbow is justifiable for simple ankylosis at a right angle, because after an excision the joint is more useful than a stiff elbow. It is also justifiable for pain. If there is any suspicion of tubercular process it seems to me that the operation should be performed as early as possible, and that it is not wise to wait until the bones have become extensively disorganized.

REGULAR Meeting, Monday, November 27, 1853.

NOTES ON PHOSPHATURIA.*

DR. PAUL THORNDIKE presented a paper with the above title.

DR. E. S. WOOD: I am very glad to have been able to hear Dr. Thorndike's paper. I thoroughly agree with him that the first class of cases to which he referred, the milder cases of phosphaturia, really is not entitled to the term phosphaturia. It is not the condition of things which at all affects the quantity of the phosphoric acid eliminated, but simply the precipitation of the earthy phosphates due to a change in the reaction of the urine, and a good deal of distinction should be made between the temporary and permanent condition. As we know, temporary phosphaturia is physiological and not pathological. It is of very frequent occurrence in the urine of perfectly healthy persons after the ingestion of a good deal of vegetable food or vegetable salts. The permanent condition, however, which results in the permanent alkalinity of the urine by a fixed alkali is dependent upon just the conditions which Dr. Thorndike has mentioned, disturbances of digestion, nervous disturbances; and such cases used to be treated sometimes by the antacids simply for the purpose of changing the character of the reaction of the urine, an erroneous treatment, unless with the idea of giving the mineral-acid tonics, which prove generally of very excellent service, but not by virtue of their antacid effect, only by virtue of their tonic effect. The quantity of the earthy phosphates which may be precipitated from the urine under such circumstances may be made to vary a good deal with the character of the food. Lime salts and waters containing lime will prevent, to a certain extent, large quantities of earthy phosphates in the urine, for the reason that chalk when united with phosphoric acid in the alimentary canal will pass through without being absorbed. The form Dr. Thorndike has spoken of under the head of phosphoric diabetes I was glad to hear him mention because those cases are in my experience exceedingly rare, and it is, I think, largely on account of their rarity that they cannot be classified under any special set of clinical conditions. In all my experience in urinary analysis I have never met with but one case of what should be considered, I think, true phosphaturia, or what has been spoken of as phosphatic diabetes. This term was given by Tessier, I think, because it had sometimes alternated with the saccharine diabetes; and the explanation was given which Dr. Thorndike has mentioned. That class of cases is always characterized by polyuria and polydypsia, with various symptoms referable to the nervous system and other organs in the body. One class of symptoms reported by Tessier was in the early stage of phthisis where there was an immense amount of earthy phosphates in the urine, with polyuria and polydypsia; the explanation is given by him that the earthy salts are derived largely at the expense of the pulmonary tissue. I have tried to find similar cases, and have received the co-operation of a number of clinicians; but I have never been able to duplicate any of Tessier's cases. I have never in early phthisis been able to find a polyuria with a large excess of earthy phosphates. The only case of true phosphaturia which I have met with since I have been connected with the Medical School was in the case of a gentle-

man whose urine I had examined from time to time for a good many years; and in 1879 a large number of analyses of his urine showed this condition. I never saw the patient himself, and do not know the symptoms. February 25, 1879, my record shows four quarts of urine passed in twenty-four hours, containing 9.6 grammes of phosphoric acid, the average being 3 to 3.5 grammes. The urine on March 7th was 3,500 c.c.; between three and four quarts on four successive days; and the amount of phosphoric acid on the 12th of March was 7.4 grammes, and the amount of urine 3,700 c.c.; no albumen and no casts. There was a little evidence of some irritation about the prostatic region which was easily explained by the age of the patient. That condition lasted but a comparatively short time, perhaps two months, and then disappeared. The polyuria continued, but the phosphoric acid fell to its normal quantity. A year or two later examination showed, instead of phosphaturia, decided oxaluria; large quantities of calcic oxalate were found in the sediment, and albumen and casts appeared later. Those have continued, and the condition of the urine at the present time is that of chronic nephritis of the interstitial type, which must have begun somewhere in 1879 or 1880. That is the only case in which I have ever been able to find those large quantities of phosphoric acid in the urine, with polyuria and polydypsia, where it was not due to the ingestion of phosphoric acid or phosphates.

One class of Tessier's cases is given as a purely nervous disease; and he considers that the nervous tissues which are rich in phosphorus are undergoing an unduly rapid metabolism, which accounts for the excess of the earthy phosphates in the urine. In all of these cases the excess of phosphoric acid is in the form of the earthy phosphates, and not in the form of the alkaline phosphates.

DR. R. T. EDIS: I was rather glad to find from the remarks of Dr. Thorndike and Dr. Wood that the notion of the relation of phosphates to the disintegration of the nervous tissue has been exploded. There used to be a good many stories in the books. One of them is quoted by Dr. Holmes in one of his non-medical works, to the effect that a clergyman used to pass a large quantity of phosphates every Monday morning; that probably had more to do with the Sunday dinner than with the sacred exercises in which he participated. A number of years ago I made some observations on myself, taking some days when I was as lazy as I could be, and others when I was busy; and I could not see anything decisive in the quantitative changes.

DR. THORNDIKE: In protesting against the use of the term phosphaturia, I only meant to find fault with it as descriptive of a well-marked clinical condition, such as one commonly reads of in books, and might be led to suppose occurred as commonly as albuminuria, for example. I did not mean to say that there was no such thing as true phosphaturia, of course.

A HOSPITAL WHILE YOU WAIT.—The Metropolitan Asylums Board of London, to provide for the rapidly increasing number of fever patients, recently had a hospital built in nine weeks, with wards all complete and with accommodation for 400 patients, 40 "charge" nurses, 50 assistant nurses and 76 female servants, every hygienic and sanitary appliance, corridors, kitchens and consulting-rooms.

SOME recent investigations undertaken to ascertain the nature of the germs of vaccine, by Buttersack, at the Imperial Hygienic Institute of Berlin, were detailed by him at a meeting (December 15, 1893) of the Society of the Physicians to the Charité, and are of interest.¹

All pathologists are agreed that the specific microbes of vaccine must exist in the clear lymph of the vesicle, and that these micro-organisms are the agents of the vaccinal infection. The experiments of Straus, Chambou and Menard (1890) have proved that the lymph when filtered through a plaster filter loses entirely its properties,² so that its virulence is due to the figured elements which it contains. Various bacteria have, it is true, been found in the vesicles and pustules of vaccinia (bacterium termo, proteus vulgaris, staphylococcus pyogenes aureus, cereus albus, etc., also peculiar cocci discovered by Hallier, Quist, Voigt, Garré, and others), but none have yet been proved to possess the peculiar properties of vaccine.

Buttersack bases his investigations on the assumption that the real germs are in the lymph of the vesicles, but are invisible, and that any microbes hitherto found there are simply accidental, unessential, or accessory. The vaccinal lymph is clear and transparent; the elements which it contains must then have the same index of refraction as the liquid itself. If this were otherwise, the lymph would be turbid, and the more so the greater the number of elements in it not translucent. Now, in order that microscopic elements may remain thus invisible in lymph, whose index of refraction is about 1.34, it suffices that the difference of their indices of refraction from that of the liquid which contains them shall be 0.1 or a little more. This difference is inappreciable to ordinary sight, especially if the observer is looking through the microscope, and the object is unknown. Even for an object that is known and not of microscopic dimensions, a difference

of index equal to 0.05 between it and the liquid in which it exists, assures its complete invisibility.

It is, then, because both the liquid and the germs refract alike that the latter are invisible in the lymph. To render visible the germs, it would be necessary to examine preparations of lymph in a medium with refractive index widely different from the ordinary. The air, whose index of refraction is one, can be utilized for this examination, and in slides of dried lymph examined without any refractive medium but the air, a method already employed by Koch to reveal the cilia of certain bacteria that do not stain, Buttersack has been able to detect a certain number of formed elements. To test the value of this mode of mounting, Buttersack first tried it on blood globules and certain bacteria of known species. All these bodies appeared in these preparations with contours incomparably more clear and well-defined than when seen in water.

The germs of vaccine, according to this authority, are not merely distinguished by their peculiarity of refraction; they are also very small, and have little tendency to aggregation in masses. Vaccinal lymph, as is well known, remains active under great dilution. The vaccinal corpuscle, moreover, seems to have different chemical properties from those ascribed to other known germs, and this explains the failure of attempts to stain it. In short, this germ is presumed to be small, pale, and unsusceptible of staining.

Buttersack has studied the lymph of the vesicles of children, recently vaccinated. This lymph, taken when perfectly clear and dried on the cover-glass, is gently washed in water and fixed to the glass slide with a couple of drops of wax and examined by means of apochromatic objectives. In these conditions, Buttersack has seen corpuscles in great number, very small, pale, always of equal size, sometimes grouped in chains. In continuing the examination, he perceived an extremely fine network constituted by pale filaments. These could always be followed to a considerable extent, and contained in their meshes an abundance of the little corpuscles above described. These filaments were preponderant in pustules, growing and completely developed, while the corpuscles preponderated in pustules in process of retrocession.

Buttersack's investigations have included one hundred vaccinated children, and always gave the same results. The slides invariably contained corpuscles and filaments in varying proportions. Control experiments were made with dried fluid obtained from phlyctenæ in different stages, from the pustules of acne, from various transudations and exudations, from normal lymph, but there was entire absence of the characteristic vaccine corpuscles and filaments.

From the point of view of culture, there was not much to expect of the ordinary media which have thus far proved refractory under the manipulations of other experimenters. Buttersack has attempted preferably the culture of the germs in the living animal. He introduces under the skin of a calf a capillary tube filled with vaccine lymph. At the end of three or four days

¹ Deutsche Med. Woch., No. 51, 1893; Médecine Moderne.² Charcot: Traité de Médecine, t. II, p. 177.

there appears at the site of inoculation an intense infiltration, the liquid of which contains filaments. This liquid by inoculation in other animals and in children, gives rise to typical vaccine vesicles. Buttersack anticipates the objection that these filaments may be nothing but fibrine. The vaccine filaments are everywhere of uniform thickness; not so with fibrine filaments. Moreover, the former cross and intercross with a clearly defined angle, and without fusing together, in this respect markedly differing from fibrine. Fibrine takes certain staining fluids; the vaccine filaments do not.

Lastly, the elements of vaccine undergo a certain biological process of development, as Buttersack's experiments show. The principal of these experiments consisted in the introduction of sporiferous lymph in a deep cutaneous wound of the forearm; six hours afterwards he found several isolated filaments in the serum of the wound; at the end of twelve hours, they were much more abundant; twenty-four hours after, the complete network was formed, and on the third day spores luxuriated, and became predominant.

Hence, then, the constant presence of these elements on vaccinal lymph, their absence in other affections, their biological evolution in harmony with the clinical syndrome, lastly, their transmission by inoculation tend to prove their importance in the act of vaccination.

It remains to be established whether these elements exist also in small-pox. Some researches undertaken on some small-pox patients at three different towns, incline Buttersack to believe that they do. In recent cases, he has observed the filaments, and in advanced cases the spores accumulated in the pustule and in the lymph of the neighboring cutaneous region. The variolous substance inoculated in calves, furnished the same infiltration with the same filaments and spores as when ordinary vaccine lymph was the infectant material.

A fuller, illustrated report, of these observations will be issued in an early publication of the Imperial Hygienic Institute. In this connection our readers will recall the report of the work done in this direction by the late Dr. S. C. Martin, of Brookline, published in this JOURNAL, December 14, 1893.

PROPOSED LEGISLATION CONCERNING CAPITAL PUNISHMENT IN OHIO.

THE Ohio Legislature is to have under consideration this session a bill to substitute physiological experimentation for capital punishment, or rather to make the criminal subject first to experiment and then to execution. The proposed bill, which is offered as an amendment to the present act dealing with capital punishment, provides:

(1) "That all persons sentenced to death by any court having jurisdiction in the State of Ohio, shall be held as subjects for experimental research; that such experiments shall be conducted in the interests of science and society,

and shall be regulated by approved rules of humane treatment to avoid all unnecessary pain; that in the preparation for such experiments, where pain would be occasioned, anæsthetics shall be administered to the extent of complete insensibility to pain, and during the progress of the experiment narcotics shall be judiciously used to allay any pain, and the condemned person shall not be maltreated in any way; that after the conclusion of such experiments the criminal shall be again anæsthetized and put to death while in a deep sleep and entirely insensible to pain; that the executioner shall be an expert physiologist duly appointed and authorized by the State, and that such appointments to execute and conduct such experiments shall be vested in the Governor, and shall consist of one executioner and five assistant physiologists, with a like number of deputies, who shall hold their office for the term of good behavior, except upon proof of incompetency; and no one so appointed shall be removed without sufficient cause, which shall be left to the discretion of the Governor, and that all appointments to fill vacancies caused by death, resignation or removal, shall be made as prescribed in the foregoing.

(2) "All executions of the death penalty, according to the provisions of this bill, shall take place within a building provided for that purpose, and so constructed as to safely and comfortably lodge all capital criminals until the completion of the execution; that such criminals shall be in the custody of a warden or deputy warden and board of managers, who shall provide for their safe and comfortable keeping; that the execution of the sentence shall commence on the day fixed by the judge passing the sentence, unless a suspension of execution be ordered by the Supreme Court or two judges thereof.

(3) "That no one shall be present at experiments and executions except the warden or deputy warden in charge of the prisoner, the executioner, assistants, and deputies, and those who have duly qualified themselves to comprehend the experimental work; that such qualifications shall be determined by a board of examiners, who shall issue a certificate which shall admit the holder to witness the experiments and executions; that at the conclusion of each execution a written report shall be required of the body of physiologists which shall contain a correct account of the result of the experiment and execution, and that such a report shall be made within thirty days from the infliction of death, and recorded in the archives of the institute."

It has often been suggested, with some degree of reason, that criminals condemned to death be allowed reprieve on the condition of subjecting themselves to experiment; but certainly to pass a law that such persons shall be used for vivisection and then executed even while still under anæsthesia, is as far beyond all bounds of legitimate action as it is abhorrent to the sense of humanity.

Before the same Legislature we understand another bill has been introduced, prohibiting the performance of circumcision. Are these proposals to be classified under tragedy or under comedy?

MEDICAL NOTES.

SOME VACCINATION STATISTICS. — The official report of the epidemic of small-pox which occurred in the borough of Halifax, Nova Scotia, between the middle of March, 1892, and the end of September, 1893, shows that there were 513 patients admitted to

hospital, 44 of whom died, a mortality of 8.5 per cent. The vaccinated cases numbered 425, with 8 deaths, or 1.8 per cent. mortality; the unvaccinated, with 36 deaths, or 40.9 per cent. mortality. There were two cases in revaccinated persons, one having been "revaccinated inefficiently five years ago," the other "revaccinated thirty-four years ago."

TO PERPETUATE DR. BLANCHE'S MEMORY.—The City of Paris has changed the name of the Rue des Fontes to Rue Blanche, in honor of Dr. Antoine Louis Blanche.

A GIFT FOR A VIRGINIA HOSPITAL.—The Sheltering Arms Hospital at Charlestown, W. V., has received a gift of seventeen thousand dollars from the widow of Ex-Governor Olden of New Jersey.

DEATHS FROM CARBOLIC ACID IN ENGLAND.—Between February, 1892, and November, 1893, there were two hundred and thirty deaths in England due to taking carbolie acid. One hundred and seventy-four of them were suicidal.

EXAMINATION FOR THE MARINE-HOSPITAL SERVICE.—A board of medical officers will meet, Monday, April 16, 1894, in Washington, D. C., for the purpose of examining candidates for appointment to the grade of Assistant Surgeon, in the Marine-Hospital Service. For further information address the Supervising Surgeon-General, U. S. Marine-Hospital Service, Washington, D. C.

CHEMISTRY AND READING NOTICES.—Our esteemed contemporary *The Lancet* has started a department of Analytical Records, which to Americans who are supposed not to have a very keen medico-ethical sense seems very strange. It has equipped a laboratory, and everything is grist to the scientific mill therein. We find *The Lancet* publishing analyses of champagne, lager-beer, bon-bons, cigarettes, malt, wine, tea, gin, etc. Curiously enough everything analyzed and reported upon is found to be good; so that the state of mind of *The Lancet's* chemist is very suggestive of that described in Genesis at the end of creative work.
— *New York Medical Record*.

BOSTON AND NEW ENGLAND.

SMALL-POX IN BOSTON.—Two new cases of small-pox have been reported to the Board of Health during the week ending at noon February 7th. There have been no deaths. There are at present nine patients in the hospital, all of whom are doing well.

ACUTE INFECTIOUS DISEASES IN BOSTON.—During the week ending at noon February 7th, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: scarlet fever, 47; diphtheria, 41; measles, 7.

THE PUBLIC HEALTH COMMITTEE OF THE LEGISLATURE.—The Public Health Committee of the Massachusetts Legislature for the present session consists of Senators E. B. Harvey, M. D., of Worcester County, E. G. Frothingham, of Essex County, E. A. Besson, of Essex County, and Representatives Crane, of Som-

erville, Tuttle, of Boston, Mahoney, of Boston, Johnson, of Lynn, Harvey, of Springfield, Fisk, of Dennis, Goodell, of Brookfield, and Marsh, of Hanover. It gave a hearing yesterday upon two proposed measures—one a bill to provide for medical registration, and the other for the State ownership of vaccine farms.

THE LYMAN PRIZE.—The Lyman Prize established for graduates of the Boston City Hospital, of not more than three years' standing, by Mrs. George H. Lyman, in memory of her husband, Dr. George Hinckley Lyman, who was a member of the medical staff of the hospital for many years, has been awarded this year, in two equal parts of \$150 each, to Dr. John Lovett Morse, of Boston, for an essay entitled, "A Bacteriological Study of Four Hundred Cases of Inflammation of the Throat in Diphtheria and Scarlet Fever, with Special Reference to Pathogenesis," and to Dr. Arthur Howard Wentworth, of Boston, for an essay entitled, "A Study of the Blood in Early Life." The usual prize is \$150, but no prize was awarded last year.

A REQUEST TO A NEW HAVEN HOSPITAL.—The will of Mr. Andrew L. Kidson of New Haven, Conn., bequeaths five thousand dollars to the General Hospital Society of New Haven.

THE BOARD OF MEDICAL EXAMINERS, M. V. M.—By a recent order of the Commander-in-Chief, the Board of Medical Examiners, M. V. M., is now constituted as follows: Lieut-Colonel Freeman C. Hersey, Medical Director Second Brigade, President; Lieut-Colonel Edward J. Forster, Medical Director First Brigade; Major Otis H. Marion, Surgeon First Regiment Infantry, Recorder. Brigadier-General Herbert L. Burrell and Major Charles C. Foster are relieved from further duty on the Board by the same order.

THE ALLEGED DEATHS FROM VACCINATION IN LOWELL.—The two deaths in Lowell week before last which were reported in the daily papers with much heading as due to vaccination, were due to other causes. From official sources we learn that the death returns gave "tonsillitis" and "bronchitis" as the causes. The several cases of "bad arms" which came to notice were "considered due not to impure vaccine, but to the introduction of foreign micro-organisms by faulty technique."

NEW YORK.

INSANITY STATISTICS.—The annual report of the State Board of Charities, submitted to the legislature February 1st, shows a total increase in the number of insane in the institutions of the State from October 1, 1880, to October 1, 1893, of 8,842. The increase in population from 1880 to 1892 was 28 per cent., while the increase of the insane in the institutions was 83 per cent. A part of this increase, it is stated, may be accounted for by the greatly increased accommodations, by means of which many insane had been taken from their homes to institutions. Besides, the better care of the chronic insane has doubtless considerably pro-

longed their lives. Still, the Board believes that the increase is not wholly accounted for by these causes. The number of patients in the various State hospitals for the insane on October 1, 1892, was 7,484; the number of admissions during the year ending September 30, 1893, was 2,586, and the total number under care during the year, 10,070, as against 9,435 the preceding year. The number of insane in the county and city poorhouses and asylums of the State, exclusive of New York and Kings Counties, October 1, 1893, was 610, as against 857 October 1, 1892. The number of admissions to the asylums of New York City during the year ending September 1, 1893, was 1,699, as against 1,592 admitted the previous year. Overcrowding still continues in the asylums of New York. The one on Blackwell's Island, with a capacity for 1,110, has 1,762 inmates, and that on Ward's Island, with a capacity of 1,620, has 2,349 inmates. Other buildings however are to be fitted up on Ward's Island which will accommodate 1,200, and thus relieve the overcrowding in these institutions.

MORTALITY. — The general health of the city, as indicated by the mortality reports, continues very fair for the mid-winter season. During the week ending February 3d, there were 848 deaths. Of these, 18 were from influenza, a decrease of six from the preceding week. The contagious diseases in general, however, show some increase, and the deaths from measles amounted to 28. Diphtheria continues to be the most prevalent and serious, and shows a mortality of 58 for the week. The deaths from scarlet fever numbered 20. During the week an unusually large number of births were reported, 1,187. As a rule, a large number of births are left unrecorded by physicians and midwives, and of late the Board of Health has been making a house-to-house canvass of the city in order to ascertain approximately the number of births which occurred in 1893.

Miscellaneous.

CREMATION IN PARIS.¹

In November, 1887, a law was passed allowing the French citizen to dispose of his dead by cremation instead of burial, if he so chooses. All such cremation is carried on under the control of the Board of Health and under the surveillance of the municipal authorities, who issue permits for incineration only upon a written request from the legal representative of the family, accompanied by a certificate of the cause of death from the attending physician and the consent of a sworn medical official appointed to verify the cause of death in such cases. The ashes after cremation may not be placed, even temporarily, in any but regular places of sepulture.

At the present time Paris is the only French city possessing a cremation establishment. Previous to the law of 1887 she had obtained the permission of the government to build a crematory to dispose of the hu-

man remains from the medical and anatomical schools; and this plant served for the first incinerations.

The law prescribes most minutely the details of the procedure and the preparation of the body. The ashes are placed in an urn paid for by the family. If the urn is to be placed in a private tomb, it may be of any design; but if it is to be put in the municipal columbarium, it must have the following dimensions: height 28 centimetres, length 48 centimetres, width 28 centimetres. Urns containing funeral ashes may not be made part of any monument, but may be buried if the grave is marked by a stone.

The charge for cremation varies according to the convoy, the services being free. The cost runs from 50 to 250 francs. The expense of private cremations has been much reduced by the fact that the city is obliged to maintain a cremation furnace in constant operation day and night, in order to dispose of the remains of the 2,000 bodies annually received from the dissecting-rooms. There is only one columbarium, which contains 354 cases.

The statistics of cremation in Paris up to the first of last November are as follows:

	Incinerations at request of family.	Remains of bodies from hospitals, etc.	Embryos under four months.
1889	49	483	217
1890	121	2,188	1,079
1891	134	2,369	1,238
1892	159	2,360	1,426
1893, to October 31st,	150	1,965	1,194
	613	9,414	5,151

In spite of the advantages from a sanitary point of view, and of the ease and cheapness of procuring service, cremation has won favor but slowly in Paris, and even more slowly in the rest of France. The government has done much to extend the use of incineration, but with very little effect. Two facts have especial bearing on this: the publicity attending cremation and the religious repugnance of a Roman Catholic people.

WHAT "MENTAL CURE" IS.

In a recently published volume entitled "*The Philosophy of Mental Healing*," the author, Mr. L. K. Whipple, gives the following definition of what mental healing is in the minds of those devoted to that science:

"Mind is the intelligence of the body. Mind thinks; its thought is registered on the body in physical element. The thought is a model of the idea; the body and its conditions are a constructed copy of the model. When the model changes the copy correspondingly changes. This rule holds good with regard to every part of the system, but is especially true of the most finely constructed parts, because these are subjected to the quickest changes. In the finest nerve mechanism important changes frequently occur instantaneously, while in the coarser structure of bone, cartilage and ligament they take place more slowly. The instant the mental cause ceases its disturbing vibrations, nature begins natural restorative activity in every part of the physical system; this is as certain as that water will run down hill. . . . When these truths are intelligently comprehended the fact becomes evident that disease—whatever its name or nature—must originate in some mental activity afterwards registered in the body, where that mode of action is outwardly expressed. Knowledge of this fact is the key to accurate diagnosis,

¹ La Médecine Moderne, 1893, 103.

and a sure guide to adequate mental therapeutics. . . . Thorough knowledge of the natural laws of human existence, based upon intelligent understanding of the fundamental principles of spiritual life, each thinking mind has power to reverse every wrong mode of action, and to establish right conditions. Exercise of this power in removing disease is a legitimate mental cure. Its nature is metaphysical.

OBITUARY.

MEMORIAL OF HOWLAND HOLMES, A.M., M.D., OF LEXINGTON, MASS.

At a meeting of the Middlesex East District Medical Society held at Wakefield, Mass., January 24, 1894, the following memorial and resolution was presented and adopted:

The members of this Association desire to place upon record their high appreciation of the life, character, personal and professional worth of our late associate-fellow, Howland Holmes, A.M., M.D., of Lexington, Mass., whose sudden death has brought grief to us all.

Dr. Holmes was born in Halifax, Plymouth County, January 16, 1815, and was a lineal descendant on his mother's side from John Alden, the Pilgrim, and on his father's side from John Holmes, who was in Plymouth in 1632. He was fitted for college at Bridgewater, Mass., and Exeter, N. H., and took his degree of A.B. from Harvard in 1843, A.M. in 1846, and that of M.D. in 1848. Dr. Holmes was made an associate member of this Society soon after its organization, and so long as he lived was a constant and interested attendant upon its meetings, endeavoring always to contribute his full share to their interest and profit.

From this time forward his genial presence will be sadly missed. He closed a long, a useful, an honest, and an honorable life in a moment. The swift-winged messenger of death met him while returning to his home from one of his accustomed errands of mercy. That messenger came to him unheralded, and in a twinkling he left us and was gone.

We tender our heartfelt sympathy to his afflicted family in this great trouble, and point them to the consolation to be derived from the knowledge of his long and useful life, and that he was spared the mental and physical infirmities of old age.

Dr. Holmes was distinguished in a marked degree for his clearness of perception, the firmness of his convictions, his courage in expressing them, and his geniality of manner. He was highly social in his nature, and, aside from his own domestic circle, enjoyed the society of none more than that of his professional brethren. We knew him long and knew him well.

THERAPEUTIC NOTES.

THREE CORYZA PRESCRIPTIONS.—In a recent discussion before one of the Parisian medical societies, the three following prescriptions were given, as having been found of value. M. Grellety advised the free use of this powder, especially in the early stages:

R Betol 2.5 grammes
Menthol 0.25 grammes
Cocaine 0.50 grammes
Powdered burnt coffee 1.5 grammes M.

M. Huchard recommended a snuff containing less cocaine:

R Bismuthi subnitrat 15 grammes
Camphor 5 grammes
Cocaine hydrochloratis 0.05 grammes M.

M. Julien preferred an ointment to a dry powder:

R Vaseline 30 grammes
Acid. borac 5 grammes
Menthol05 to 20 grammes M.

A REMEDY FOR TRIGEMINAL NEURALGIA.—Nægely¹ recommends the following method for quieting the paroxysms of trigeminal neuralgia, hemicrania, globus hystericus. The great horns of the hyoid bone are pressed by the two thumbs of the patient or physician up against the larynx for a minute or ninety seconds. While he cannot give an explanation of the action, he has found it effective in many cases.

GASTRIC NEURASTHENIA.—Rummo and Braccini² recommend the following combination of the zinc salts in acute neurasthenia, especially when attended by gastric symptoms:

R Zinc phosphidi 0.1 gramme
Zinc bromidi 1.0 "
Quinine bromohydrat. 1.5 "
Ext. nucis vomicae 0.15 "
Misce. Ft. pill., No. xxx. Sig. One three times a day.

ALBUMINURIA AND PHOSPHATURIA.—In a communication to the Académie de Médecine, M. Robin gave the following outline of treatment for cases of phosphatic albuminuria: The first point, in importance, is to combat the nutritive disturbances, and the catabolism which leads to an undue elimination of phosphorus. Following this the attention should be given to preventing the destruction of the blood globules and to controlling the albuminuria. The hygienic treatment consists in moderate exercise, massage and complete intellectual rest. The diet should contain, above all else, vegetables, rich in phosphorus and potassium, as beans and lentils; white flour and sugars which retard oxidation are contraindicated. Beef, mutton and shell-fish are allowable, but meats rich in gelatine, and fish are to be forbidden. As medicinal treatment the following are especially commended for the nutritive troubles: arseniate of soda, cod liver oil, the glycero-phosphates, hypophosphites, sulphate of quinine. Iron, arsenic and strychnine combat the destruction of the blood globules; while gallic acid, and the iodo-tannic preparations give good results in controlling the albuminuria.

Correspondence.

THE EXPERIENCE OF TWO WOMEN PHYSICIANS WITH SMALL-POX.

BOSTON, February 3, 1894.

MR. EDITOR:—Dr. White's personal experience with small-pox, related in the *Boston Medical and Surgical Journal* recently (January 24, 1894), recalls our own vivid acquaintance with the same disease.

In the summer of 1870, we were visiting hospitals in Paris, being, with Dr. Mary Putnam Jacobi, the only medical women there. We were in good health, and full of enthusiasm about our work, but were also intensely interested in the Franco-Prussian War, which was then in progress. Since the 7th of August, Paris had been declared in a state of siege, and its bombardment was only a question of time.

Small-pox was epidemic in the city, the mortality from the disease averaging about four hundred deaths a week. There seemed to be no public or private precautions taken against its spread, and no special hospitals devoted to the care of its victims. A personal friend of the family with whom we boarded, died of confluent small-pox, and his friends watched with him several nights before his decease.

¹ Mercredi Médicale, 1893, No. 31.

² Semaine Médicale, 1893, 64.

He had a public funeral in one of the churches to which written invitations were sent, according to the custom there.

Naturally we were free from fear or apprehension of the disease, so that when we decided to follow the service of Dr. Hérard, in the old Hotel Dieu (the new one was not then ready for occupancy) the fact that one of his wards was devoted to small-pox, did not serve to deter us from our plans. We took the precaution to be vaccinated, however, for the first time since infancy. It was hot weather, and it was found months later that the virus had been kept some days, and was probably inert. At all events, the vaccinations did not take, and in consequence we considered ourselves safe from infection.

Our first visit with Dr. Hérard was September 2d. At the close of the regular visit we accompanied him to the small-pox ward, which contained twelve beds, all occupied. The instant we entered the ward, we noticed the peculiar musty, sickening odor, which seemed characteristic of the disease. That day there were no cases of unusual severity, but on later visits, we saw cases both confluent and hæmorrhagic, extremely repulsive to look at, with faces swollen beyond recognition. Stupor or delirium fortunately made these patients partly oblivious to their sufferings. Very little treatment seemed to be given, and in no cases were the faces protected in the slightest degree. Therefore all we gained, was some knowledge of the appearance of the disease in its successive stages.

We had decided to remain in Paris during the siege, under the protection of the American minister. The Republic had been proclaimed September 4th, the city was being provisioned, troops were arriving from the Provinces for the defence of Paris, and were being quartered on the inhabitants. We were well and anxious to stay, when on the 13th of September, there appeared in the papers a peculiarly strong appeal from General Trochu, the Military Governor of Paris, in which he implored all foreigners and those not absolutely needed, to leave the city at once, as the difficulty of providing food would be so great that "useless mouths" must go.

The following day we went to the American Embassy and were advised to leave the city that evening. Realizing that as soon as the city gates were closed, we should be cut off from communication with the outside world, we at last reluctantly resigned ourselves to going in the last train that would be allowed to leave the city. The Prussians were already in Versailles, and the shorter routes to England had been destroyed by blowing up the bridges. Therefore we were obliged to go by the way of Dieppe and Newhaven. Since we were allowed to carry only hand baggage with us, it became necessary to pack and store all our belongings. This, with other matters, kept us very busy during the hours that remained before our departure, so that, when we took our places in the crowded train at six o'clock, we were thoroughly tired out.

We reached Dieppe at one A. M., and drove to the boat in an omnibus. It was three hours before we started, and the wait was very tiresome. The boat was small and uncomfortable, and so overcrowded that it was impossible to find proper accommodation, so we were obliged to lie in cramped positions on seats next the outside rail on deck. The night was damp and raw, and we could not obtain extra coverings, so we alternated with cold and heat all through that wretched night. The passage took seven hours, nearly twice its usual time. We finally landed in Newhaven, about eleven A. M., with excruciating headaches, vertigo and fever, and aching all over. We secured comfortable seats in a compartment of the train in waiting, and bought some biscuit and fruit, as we felt unable to take a breakfast at the hotel near by.

London was reached in about two hours, and we drove at once to the hotel. We retired early, but were burning with fever or in profuse perspiration all night, while our headaches were constant and severe. We had no lumbar pain, however, but a bruised feeling all over. In the morning we wondered that we felt no better, but were inclined to attribute our discomfort to the fatigue and excitement of the few previous days. We felt that quiet and rest for

a time would restore us to our wonted health. Neither of us suspected we might be suffering from premonitory symptoms of small-pox.

Throughout the day following our arrival, September 16th, we were never free from chilly sensations and high fever, with a sense of extreme prostration, headache, and complete anorexia. No relief followed the taking of hot baths, hot punch and Dover's powder; indeed, we felt even worse. The following day, all our symptoms became intensified. We remained in bed, and concluded we must be in for something serious.

Up to this time we had done what we could for ourselves, and kept our real condition as far as possible from our friends, but we knew they felt very anxious about us, and so we decided to call a physician.

Accordingly, a note was written to Miss Garrett, M.D. (now Mrs. Garrett-Anderson) the only woman physician in London. She was the only woman graduate of Apothecaries' Hall in London, the doors being closed to other women after she obtained her degree. Later she had taken a degree at the École de Médecine in Paris, being its first woman graduate. We already had a letter of introduction to her, which we enclosed in the note asking her to visit us professionally. She promptly responded to the call, and found us with temperatures of 104° and 105° respectively, with pulses to correspond, but reserved her diagnosis. Cooling draughts and quinine were prescribed, but with little relief.

The next day, September 18th, the temperature had lessened slightly, but the lassitude was still extreme, and there was a peculiar feeling all over, as if one were incased in india rubber half an inch thick. We were obliged to stay in bed all day, too wretched and miserable to care for anything. All through that night, the one who later had the most eruption complained of a peculiar taste in the mouth and throat, with considerable soreness, and both were conscious of an odor which for the first time made us think of "small-pox." The feeling of shot under the skin of the forehead was marked. We mentioned to each other our suspicions that we were suffering from small-pox, and anxiously waited for daylight to confirm the diagnosis. In the morning faces and parts of the body were seen to be covered with blotches like measles, and the fever and discomfort had moderated somewhat.

Naturally our friends were much alarmed, and thought of small-pox at once, as they knew it was in Paris. We persuaded them to keep away until after the doctor's visit. The moment she entered the door she exclaimed, "Why, is it possible you have the measles?" But as she approached nearer, she added, "Oh! I am afraid it is the small-pox." A close inspection proved the correctness of the diagnosis, and then we began to consider what we should do. At that time there was no good small-pox hospital in London, though one was built soon afterward. No hospital would take us, the hotel proprietor was in despair at having such a dreaded disease in his house, and naturally eager to get us away at once, while we were equally eager to depart, but in a quandary where to go. Miss Garrett was full of sympathy, and said she would see what could be done, and meanwhile would send us at once a nurse with directions about our care. Our friends were banished from our room, and all vaccinated as soon as possible.

An hour or two of waiting intervened, when a tap at the door was followed by the entrance of a good, motherly-looking nurse who had received instructions what to do for us. In a short time we were dressed and thickly veiled, put into a cab, and carried to a private house not far away, where we were put into comfortable beds in a large room on the top floor. The occupant of the house had been away on the Continent for some weeks, and the opportunity had been taken to have a house-cleaning. The two upper floors were thoroughly dismantled, with carpets up, so they were in the right condition for our reception. No one was on the floor with us but our good nurse. Antiseptic precautions were instituted at once.

With the exception of our banker, who had been a victim of the disease in Paris, our friends were not allowed to

know of our whereabouts, although they were kept acquainted with our progress. We had the best of care, and every reason to be thankful at our good-fortune.

The partial remission of symptoms the day the eruption appeared, was of course, but temporary, and fever appeared with renewed energy that evening. The fever and restlessness caused by the discomfort and excessive itching was so great that the temperature rose again to 105° in one case, and continued at that height several successive days. The eruption rapidly extended over the body, and to the feet which were much swollen and painful. Sleeping-draughts were a necessity, and the feet were wrapped in soothing lotions, kept constantly wet. The other case was milder, though the temperature frequently rose to 104°.

Our room contained two large windows, which were kept open continually, but darkened by heavy curtains, while a constant fire was kept in the open fireplace for ventilation. A feeble light was supplied by a lighted candle placed behind a screen. In this way the light was kept from our faces, and the air was kept out by the manner in which they were treated. Our faces were bathed with a solution of aromatic vinegar, which allayed the itching, then glycerine applied with a soft brush, and finally a covering of soft linen with apertures for the eyes, nose and mouth. This process was repeated frequently, and undoubtedly was of benefit. Every day a large portable tub was wheeled into the room, and each in turn carefully lifted into it and bathed in tepid water containing oatmeal and a disinfectant. This was accomplished by squeezing the water from a sponge over the surface of the body, which was afterwards dried by patting gently with soft warm towels. Then we were wrapped in soft old linen sheets. This daily bath and change of linen was very cooling and refreshing, and added very materially to our comfort. It was supplemented by sponging surfaces where the eruption was thickest p. r. n.

All clothing, bed-linen, and towels were daily placed in a tub, and disinfected with Condy's solution before being sent to a special woman who did no other washing. All books and papers we handled until well, were either burned or disinfected by baking after we had used them. All letters we wrote when convalescent, were also baked before mailing them. No one contracted the disease from us, which was a comfort.

The papules on the face rapidly developed into vesicles, and those on the body followed more slowly. The burning and itching, especially in the face and feet, was intense, and the hands were kept tied up in linen to prevent scratching. The second week the eruption began to dry up, and the swelling and heat to subside.

Our treatment medically was quinine in an effervescing mixture with carbonate of ammonia, sedatives as needed, chiefly chloral or morphine, stimulants, and a nourishing diet. Milk was chiefly depended upon at first on account of the soreness of the mouth and throat. Neither case had trouble with the eyes. Indeed, it looked peculiar to see a clear circle around the eyes free from eruption, as if protected by glasses. The scalp was not so free from invasion, however, and later the hair fell out, but was rapidly renewed.

The milder case was confined to the bed about ten days after the eruption appeared, and the other two weeks, but was forced to return to bed again for three days on account of an unusually severe attack of pleurodynia contracted by sitting too near an open window the first day she sat up. The third week both began to drive out a little, and in three weeks we joined friends in Scotland. Strength returned rapidly; and on our return to London a fortnight or so later, our physician could hardly recognize us. The disease left no marks, only discolored spots that were noticeable for some months, and eventually disappeared entirely.

It was rather remarkable that we had the disease at the same time, the eruption making its appearance on both the same day. We considered it very fortunate, and it did much to keep up our spirits, as we were companions in misery. During convalescence we entertained ourselves by counting the crusts on each other's faces, one having over two hundred and fifty, the other not half as many.

Deaths reported 2,828; under five years of age 975; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 348, acute lung diseases 583, consumption 323, diphtheria and croup 171, typhoid fever 35, diarrhoeal diseases 34, measles 31, scarlet fever 22, whooping-cough 19, cerebro-spinal meningitis 16, erysipelas 12, small-pox 6, malarial fever 2.

From measles New York 20, Milwaukee 4, Philadelphia 3, Chicago 2, Worcester and Fall River 1 each. From scarlet fever Boston 6, Chicago 5, New York 4, Pittsburg and Cambridge 2 each, New Bedford, Chelsea and Newton 1 each. From whooping-cough Pittsburg 4, Boston and Washington 3 each, Philadelphia and Milwaukee 2 each, New York, Cincinnati, Cleveland, Somerville and Taunton 1 each. From cerebro-spinal meningitis Chicago and Worcester 3 each, New York, Philadelphia, Cleveland, Milwaukee, Portland, Lynn, New Bedford,

Holyoke, Chelsea and Everett 1 each. From erysipelas Philadelphia 5, New York 4, Boston, Haverhill and Waltham 1 each. From small-pox Chicago 4, New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,468,442, for the week ending January 20th, the death-rate was 23.2. Deaths reported 4,654; acute diseases of the respiratory organs (London) 547, whooping-cough 194, measles 84, diphtheria 74, scarlet fever 16, fever 43, diarrhoea 40, small-pox (Birmingham 6, Bradford 4, Bristol 3, West Ham, Leeds and Hull 1 each) 16.

The death-rates ranged from 15.2 in Halifax to 42.4 in Norwich; Birmingham 29.9, Bradford 22.1, Cardiff 21.4, Gateshead 18.4, Leeds 21.1, Leicester 15.7, Liverpool 26.0, London 23.7, Manchester 21.9, Newcastle-on-Tyne 20.7, Nottingham 18.7, Plymouth 38.0, Portsmouth 16.5, Sheffield 19.1, West Ham 21.0, Wolverhampton 24.5.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 27, 1894, TO FEBRUARY 2, 1894.

COLONEL JOSEPH R. SMITH and COLONEL BERNARD J. D. IRWIN, assistant surgeon-generals, U. S. A., are detailed to represent the Medical Department of the Army at the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894, and will proceed to the place designated at the proper time.

LIEUT.-COL. FRANCIS L. TOWN, deputy surgeon-general, U. S. A., is relieved from duty at Fort Porter, New York, to take effect on the expiration of his present sick leave of absence and will report in person to the commanding general, Department of the Missouri, for temporary duty in the office of the medical director of that department.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 3, 1894.

T. H. STREETS, surgeon, from U. S. S. "Bennington" and to U. S. S. "Detroit."

O. T. HIBBETT, surgeon, from U. S. S. "Detroit" and to U. S. S. "Bennington."

J. W. ROSS, surgeon, ordered to the U. S. Receiving-ship "Independence."

F. W. OLCOTT, passed assistant surgeon, ordered to the Naval Hospital, Brooklyn, N. Y.

L. W. SPRATLING, passed assistant surgeon, from Naval Hospital, New York, and wait orders.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. - A regular meeting of the Society will be held at the Medical Library, No. 19 Boylston Place, on Monday, February 12, 1894, at 8 o'clock, P. M.

Dr. H. L. Burrell: "The After-treatment of Appendicitis." Discussion opened by Drs. G. W. Gay and M. H. Richardson.

Dr. J. G. Mumford: "Compound Fractures." Discussion opened by Dr. A. T. Cabot.

Directly after the Secretary's report, Dr. W. T. Councilman will show a specimen of "Peritonitis Due to Embolism of the Mesenteric Artery."

Members are requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., Secretary.

RECENT DEATHS.

ARTHUR RAVARA, M.D., surgeon to the King of Portugal and to the San José Hospital of Lisbon, died recently from the rupture of an aortic aneurism while he was examining a patient preparatory to operation.

PAUL DIDAY, M.D., one of the leading surgeons in France, died in Lyons, January 8th, aged eighty-three years. He had been a pupil of Dupuytren and was one of the founders of the *Lyon Medical*. He was the author of several books on syphilitic and venereal diseases.

BOOKS AND PAMPHLETS RECEIVED.

The Treatment of Diphtheria. By F. E. Waxham, M.D., Denver, Colo. Reprint. 1893.

How Shall We Make Our Homes Healthy? By Benjamin J. Portugaloff, M.D. Chicago. 1893.

Fifteenth Annual Report of the State Board of Lunacy and Charity of Massachusetts, January, 1894.

Mensuration in the Physical Diagnosis of Pulmonary Phthisis. By George A. Evans, M.D. Reprint. 1893.

Marine sanitäts ordnung, III Bände, Berlin, 1893. Ernst Siegfried Mittler und Sohn. Königliche Hofbuchhandlung.

Some Reasons for the Performance of Circumcision on all Male Infants. By Alex. L. Hodgdon, M.D. Reprint. 1893.

Report of the Kensington Hospital for Women (Non-Sectarian) from October 10, 1892, to October 9, 1893. Philadelphia. 1893.

The Successful Management of Inebriety Without Secrecy in Therapeutics. By C. H. Hughes, M.D., St. Louis. Reprint. 1894.

The Johns Hopkins Hospital Reports. Vol. III, Nos. 7, 8, 9. Report in Gynecology, II. Baltimore: The Johns Hopkins Press. 1894.

Veneral Memoranda, A Manual for the Student and Practitioner. By P. A. Morrow, A.M., M.D. New York: William Wood & Co. 1894.

Transactions of the American Association of Obstetricians and Gynecologists, Vol. VI, for the Year 1893. Philadelphia: Wm. J. Dornan. 1894.

The Modern Climatic Treatment of Invalids with Pulmonary Consumption in Southern California. By P. C. Remondino, M.D. Detroit: George S. Davis. 1893.

Announcement and Catalogue of the National Medical College, Medical Department of the Columbian University, Washington, D. C., for the Seventy-second Session. 1893-1894.

The Necessity of Special Institutions for the Consumptive Poor; The First Step Toward the Complete Eradication of Tuberculosis. By H. Longstreet Taylor, A.M., M.D., St. Paul. Reprint. 1893.

How to Use the Forceps, with an Introductory Account of the Female Pelvis and of the Mechanism of Delivery. By Henry G. Landis, A.M., M.D. Revised and enlarged by Charles H. Bushong, M.D. Illustrated. New York: E. B. Treat. 1894.

Antibiographical Sketches and Personal Recollections. By Geo. T. Angell, President of the American Humane Education Society, the Massachusetts Society for the Prevention of Cruelty to Animals. Boston: The American Humane Education Society. 1894.

A Practical Treatise on Nervous Exhaustion (Neurasthenia), Its Symptoms, Nature, Sequences, Treatment. By George M. Beard, A.M., M.D. Edited with notes and additions by A. D. Rockwell, A.M., M.D. Third edition, enlarged. New York: E. B. Treat. 1894.

Antiseptics in Midwifery. By Robert Bloxall, M.D., Cantab., M.R.C.P., Lond., Assistant Obstetric Physician to, and Lecturer on Practical Midwifery at the Middlesex Hospital; Formerly Physician to the General Lying-In and Samaritan Free Hospital. London: H. K. Lewis. 1894.

A Synopsis of Clinical Surgery during the Service of Samuel H. Pinkerton, M.D., Surgeon to the Holy Cross Hospital; by Franklin A. Mescham, A.B., M.D., Assistant Surgeon to the Holy Cross Hospital, Salt Lake City, Utah, for the Year 1892. Salt Lake City: Tribune Co. 1893.

The Technique of Post-Mortem Examination. By Ludwig Hektoen, M.D., Pathologist to the Cook County Hospital, Chicago; Professor of Pathologic Anatomy in the College of Physicians and Surgeons of Chicago. With forty-one illustrations. Chicago: The W. T. Keener Co. 1894.

Relation d'une Epidémie de Choléra étude clinique et Expérimentale. Par MM. A. Mairat, Professeur de clinique des maladies mentales et nerveuses, et F. J. Bosc, chef de clinique des maladies mentales et nerveuses à la Faculté de Médecine de Montpellier. Avec four Planches et eleven Tracés dans le Texte. Montpellier: Charles Boehm. 1893.

The Relations of Urinary Conditions to Gynecological Surgery. Report of Two Years' Work in Abdominal Surgery at the Kensington Hospital for Women, Philadelphia. Report of a Year's Work in Minor Gynecological Surgery in the Kensington Hospital for Women, Philadelphia. The Causation of the Diseases of Women. By Charles P. Noble, M.D., Philadelphia. Reprints. 1893.

A Clinical Text-book of Medical Diagnosis for Physicians and Students, Based on the most Recent Methods of Examination. By Oswald Vierordt, M.D., Professor of Medicine at the University of Heidelberg. Authorized translation with additions by Francis H. Stuart, A.M., M.D. Third revised edition with one hundred and seventy-eight illustrations, many of which are in colors. Philadelphia: W. B. Saunders. 1894.

Dissections Illustrated; A Graphic Hand-book for Students of Human Anatomy. By C. Gordon Brodie, F.R.S., Senior Demonstrator of Anatomy, Middlesex Hospital Medical School; Assistant Surgeon, Northwest London Hospital. With plates drawn and lithographed by Percy Higley. In four parts. Part I. The Upper Limb. With seventeen colored plates two-thirds natural size. Part II. The Lower Limb. With twenty colored plates two-thirds natural size and six diagrams. London and New York: Whittaker & Co. 1894.

Original Articles.

RECENT OBSERVATIONS ON THE FUNCTIONS OF THE THYROID GLAND; AND THE RELATION OF ITS ENLARGEMENT TO GRAVES'S DISEASE; ALSO REMARKS ON THE THERAPEUTIC USE OF SHEEP'S THYROID AND OF OTHER ORGANIC EXTRACTS.¹

BY JAMES J. PUTNAM, M.D.,

Professor of Diseases of the Nervous System, Harvard Medical School.

THE object of this paper is to call attention to the present state of our knowledge as to some of the functions of the thyroid gland, and certain disturbances of nutrition due to its atrophy; and as to the relation of goitre to the nervous symptoms met with in Graves's disease and analogous states. I shall also speak of the therapeutic action of thyroid extracts in conditions other than myxœdema, and as to the use of some other organic extracts as therapeutic agents.

The dramatic history of the discovery of the relation of thyroid disease to myxœdema, cachexia strumiprivi, cretinism, and the so-called foetal rickets, is now, in its broad outlines, familiar to every physician, so thoroughly has public attention been aroused by the developments of the past few years. As long ago as 1856, Schiff had noticed the fatal effect of thyroidectomy in dogs; and even earlier than this Sir Astley Cooper and one or two other physiologists had made a few experiments in the same line, with varying results. In 1856 Curling described a few cases of sporadic cretinism as occurring in England; and in 1871 Dr. Hilton Fagge described others, and noted that they were characterized by atrophy of the thyroid. In 1874 Sir William Gull read his paper on "The Cretinoid State in Women"; and two years later, Dr. Ord gave a full description of myxœdema, and christened the symptom complex with its present name. He also remarked on the clinical relationship between these cases and those which had been described by Curling and Fagge, and noted that the atrophy of the thyroid made a pathological bond between them.

In 1884 came the remarkable observations of Reverdin, of Geneva, and Kocher, of Berne, who found that the thyroidectomy with which their experience in the goitrous districts of Switzerland had made them familiar, was often followed by a strange cachexia. Kocher at first thought this to be due to laryngeal asphyxia, but Reverdin a few months later recognized it as essentially identical with myxœdema. The flood-gates of physiological research were then opened, and a mass of observations began to pour in, which I have no space even to summarize.² Dr. Felix Semon, recognizing the extreme interest of the new discoveries, at once proposed the appointment of a commission of inquiry from the Clinical Society of London, the report of whose labors, finally published as a separate volume in 1888, will always be referred to as a treasure-house of facts upon this subject.

Even before the publication of this report, came the scarcely less valuable review by our own colleagues, Drs. Hun and Prudden, based on one hundred and fifty cases, and giving the details of two thorough and important autopsies. Finally, in the winter of 1891-

1892, Mr. Horsley, of London, whose name is identified with the best original research with regard to this matter, published in Virchow's *Denkschrift* and in the *British Medical Journal* (January, 1892), a comprehensive and masterly analysis of all the facts which were at our disposal up to that time, relating to the physiology of the thyroid.

Most of Horsley's conclusions have been confirmed by subsequent research; and it is now accepted by every one that the thyroid is an organ of immense importance for nutrition. A few of his views will, however, now bear revision; and a few important discoveries are to be added.

The history of the therapeutics of myxœdema was sketched anew by Dr. F. C. Shattuck at a recent meeting of the Medical Improvement Society; and I have nothing to add to his interesting remarks except to call attention to the fact that many cases of cretinism have been greatly benefited by thyroid feeding, even those where the disease had existed up to adult life. Two or three of these cases have been under the care of Dr. Osler,³ of Baltimore, to whom we also owe an investigation into the frequency of sporadic cretinism in America, showing that it is a disease of rare occurrence among us.

It is probable that the thyroid is not, as Horsley thought it was, a hæmopoietic organ of real significance (Gibson⁴ and others, and among recent observers, De Quervain⁵).

It is practically certain that the functions of the thyroid are not related to those of the spleen (De Quervain⁶). Later observations have indeed made it more and more probable that it is not safe to regard secondary enlargement of an organ following thyroidectomy as a sign of compensatory activity. This is especially important as regards the pituitary body, since this is probably or possibly related to the thyroid in function. It does frequently enlarge after removal of the thyroid and so does the thyroid sometimes enlarge after removal of the pituitary body; but Vassale and Sacchi,⁷ who have been most successful experimenters with regard to the pituitary body, do not believe that the enlargement or the increase of colloid which accompanies it, necessarily means an increase of functional activity.

The interesting experiments by Breisacher [v. Horsley] with regard to the action of animal food in increasing the cachexia from removal of the thyroid have been confirmed, with slight modifications, by De Quervain,⁸ in a very recent research.

This latter observer was unable to confirm the statement of Rogowitsch, Capobianco, and others⁹ that constant demonstrable changes occur in the central nervous system after thyroidectomy.

It is not impossible that a repetition of the fatigue experiments of Professor Hodge, of Clarke University, would show that anatomical changes could be more easily induced in animals suffering from cachexia than in normal animals, and that, for this reason, anatomical changes would sometimes be present which at other times were not found. Pisenti¹⁰ has recently observed

Ital. de Biol., 1893, t. xviii, p. 385.⁶ Virchow's Archiv, 1893, Bd. 133, Heft 3.⁷ See a paper by the writer, on cases of myxœdema, etc., in the American Journal of Medical Sciences for September, 1893.⁸ Cited by Gley, Arch. de Phys. n. et p., 1894, p. 187.¹ Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society at the meeting, December 20th.² See a review, with original observations, by Dr. F. P. Kinnicutt, New York Medical Record, xlv, p. 449.

the formation of small cavities, apparently of vascular origin, in the spinal cord of dogs who had survived thyroidectomy for a number of months.

The thyroid gland is found in all vertebrate animals.¹¹ It is formed by an invagination of the pharyngeal wall, and is believed by most embryologists to serve as a digestive gland, even in the lowest animals where it exists. I mention this point because a recent writer¹² has proposed the view that its functions are, in a broad sense, respiratory, and that this is indicated by its anatomical relations to the branchial clefts. It is supposed by him that its secretion in some way assists the oxygenation of the tissues. I am not able to say whether there is any real foundation for this theory or not, but Poehl¹³ who has for several years been studying the chemistry and physiology of spermin, finds that this, too, has a powerful influence on oxidation, so that it is a constituent, not only of Brown-Séquard's testicular emulsion, but also of many glands and organs, and among them the thyroid.

The gland shows itself at an early period in the human embryo and, according to Horsley, it probably begins its secretory functions by the sixth or seventh month of foetal life. It is not known upon what principle the efficiency of the secretion depends; and the fact that it remains active after it has passed through the walls of the stomach, as well as after precipitation by alcohol, has not as yet cleared up the mystery, though it indicates that the active principle is a sort of ferment. The adult gland is made up of spaces containing colloid material and lined with epithelium. It is, however, doubtful whether the colloid is more than a vehicle for some more active agent. Certainly its chemical structure may change somewhat without its efficiency being destroyed. It has been clearly shown that when the gland is injured¹⁴ or undergoes such changes as are seen in Graves's disease and even in phthisis¹⁵ there is a strong tendency to a modification of the gland-structure, with arborescent arrangement of the tissue, higher, cubical epithelium and without colloid.¹⁶ Yet myxœdema does not necessarily or even usually come on under these circumstances.

We cannot say with confidence that the gland thus altered remains in all respects as efficient as before, but even a very small part of an altered goitre is enough to ward off cachexia of serious amount. A number of cases are on record, one of which was observed by myself, where goitre with nervous symptoms passed over into myxœdema. It is a curious fact that the outbreak of the myxœdema, in my case, was attended by an enlargement and hardening of the altered thyroid, and that these peculiarities diminished during improvement, and increased again during a relapse.

Greenfield,¹⁷ who has recently studied the subject, regards this tendency of the gland to change its structure in Graves's disease as an evidence of increased glandular activity in that affection. But in view of

the fact that a very similar, if not exactly the same change occurs as a result of injury and disease (phthisis) the assumption cannot be accepted as certain. The fact that this change occurs after removal of part of the gland (Halstead) suggests that it means increased activity, but in Canizzaro's experiments the gland was injured but not mutilated, yet a similar change occurred.

Another fact, which is important in this same connection, is the following: It was at first thought that rabbits were less susceptible than the carnivorous animals to the bad effects of thyroidectomy; but the researches of Gley showed that their survival after operation was due to the fact that in these animals (and, as it seems, in many others as well), besides the main body of the gland, accessory glands or "glandules" are present which had commonly been overlooked when the main body of the gland was removed. The literature of the "glandules" is already a large one, and I will here refer to only one point concerning them. These glandules have an embryonic structure; and although they grow larger after removal of the thyroid and to some extent seem to ward off the threatening cachexia, yet their structure does not necessarily change to that of the adult gland.¹⁸

If this observation is correct, the statement which has been made that the embryonic nodules found even in the adult human thyroid (Wölfler) develop under certain conditions into a more highly differentiated structure, may need revision.

Although it has been proved that the myxœdematous cachexia does not occur after partial thyroidectomy, provided about one-quarter of the gland is left behind, yet it is not to be assumed that even this incomplete removal of the gland is of indifference as regards the nutrition of the organs and tissues of the body. This is a subject of practical interest, and some important experimental evidence has been brought forward in regard to it since Horsley's paper was written.

It has been found that the preservation of the glandules of Gley, though it usually prevents the worst forms of cachexia, does not prevent the gradual development of a series of changes affecting the bones, the skin, the ovaries, and many other organs, especially if the animals operated on are young (Hofmeister,¹⁹ De Quervain). Gley and Rochon-Duvigneaud²⁰ have recently studied with care a series of changes occurring in the eye, under these same conditions. The practical question is this, To what extent must the thyroid be mutilated, or atrophied, or diseased before some of the nutritive effects due to lack of its influence begin to make their appearance? A partial answer to this question is perhaps furnished by the fact that there are disturbances in nutrition, not identical with myxœdema but presenting one or another symptom analogous to those met with in that disease, for which thyroid treatment seems to be useful. It is needless to say that this reasoning should be used only with caution, and that no positive conclusions can be drawn as to the real value of these preparations, either as means of treatment or as pointing to a deficiency of the normal thyroid secretion.

The first person to use the thyroid of animals for other affections than myxœdema, so far as I know, was Dr. Barron of Liverpool, who, noting the fact which must have impressed every one, that patients

recovering from myxœdema frequently lose weight with extreme rapidity, the loss going even beyond the limit of health in some cases, suggested the employment of thyroids in ordinary obesity. I am not aware whether he has continued his investigations or not, but in a private letter, received in May, 1893, he stated that he had used the treatment in five cases, and in three of them with marked effect.

Acting on this suggestion, I have tried the same treatment in several cases during the past year, with the following results: One patient lost 33 pounds in three months, falling from 270 to 237, but here the influence of the treatment seemed to cease. When it was suspended for a month he regained seven pounds, which he again lost on resuming the treatment, but I have not been able to reduce his weight below 237 pounds even by giving fifteen grains of the thyroid daily. No change was made in his diet or habits. His general health showed a marked gain during the thyroid treatment.

A female patient, treated by Dr. Coggeshall, at the Boston Dispensary, lost 47 pounds in four months.

On the other hand, a female patient of my brother, Dr. C. P. Putnam, who weighed 240 pounds at the beginning of the treatment, after losing five pounds the first week, seemed to be no longer affected; and I have had three or four other patients in whom only a temporary loss of weight (up to fourteen pounds in one case), or none at all, has occurred. Possibly, larger doses might have had more effect.

It seems clear from the many experiments which have now been tried, that healthy persons are not so easily affected in an injurious way by the thyroid treatment, though certain symptoms, especially an increase in the pulse-rate, occur with considerable regularity.²¹ It would seem that we do not yet know the conditions which make one person a suitable subject for this treatment and another not so. It will be interesting if it turns out that the loss of weight, even when it occurs, cannot be made to go on indefinitely.

Another therapeutic use of thyroid preparations is in the treatment of diseases of the skin, especially in psoriasis, eczema, and xeroderma. The first of these cases was brought forward by Dr. Byrom Bramwell at the annual meeting of the British Medical Association, August, 1893;²² and the photographs which he there showed were very impressive. Unfortunately, one of these cases afterwards relapsed, and not all the more recent observers have been equally successful, even in their primary results. Dr. Hartley²³ obtained favorable effects, and Dr. Arthur T. Davis²⁴ likewise, while Talfourd Jones²⁵ experimented on a case of psoriasis, with the apparent result of making the disease spread. Lesley Phillips²⁶ obtained improvement in a case of xeroderma but none in three cases of psoriasis and one of eczema. It may turn out that the remedy is useful only in a certain class of these cases, or that it acts indirectly by exerting a psychical influence.

The history of therapeutics shows that new remedies sometimes have a mysteriously good effect. It is highly probable that these effects do not occur through mere coincidence, and are not wholly to be explained

by the assumption that the most favorable results are the first to be made public. The researches of the past few years have taught us that psychical influences can be counted upon to affect the nutrition to a degree formerly not dreamed of, and the effects of the new remedies must be studied anew from this standpoint. It is noteworthy that eczema has been favorably influenced by hypnotism pure and simple, and that good results have followed injections of testicular fluid in eczema, leucoderma, ichthyosis.²⁷ Eccles²⁸ has used spermin in similar cases with favorable effects.

Finally, Vermehren, of Copenhagen, has made an interesting series of experiments with thyroid preparation, in various conditions of impaired nutrition, with the special view of testing their action on some of the changes of old age.²⁹ He first treated three cases of myxœdema with thyroids, and gave also measured quantities of food, and followed the urea excretion. This increased in the course of the first five days in all three cases, finally reaching twice or three times the amount noted for the period before the experiments were begun. In one case it then remained at the maximal point during the continuance of the treatment, so long as the experiments lasted. In the other two cases it fell rapidly, after the first rise, but in one of these it rose again at a later time. A small part of this increased excretion of urea was found to be probably referable to an increased absorption from the intestine. The patients also lost fat largely, but the rate of loss was not estimated.

The non-myxœdematous patients experimented on were: (1) A boy of seven years, with fracture of the tibia; (2) a girl of seven, greatly emaciated and perhaps infected with tuberculosis; (3) a woman of twenty-eight, with chlorosis and gastric catarrh; (4) a man of fifty-two, but very old for his years, with chronic alcoholism; (5) a man of sixty, also old for his years, with chronic bronchitis; (6) a man of sixty-two, with varicose ulceration of the leg.

The study of the urinary excretion seemed to the author to warrant the conclusion that in the cases of the young persons the only positive effect of the thyroid treatment was a moderate diuresis, while with the elderly patients changes occurred like those seen in myxœdema, though to a less degree. It is obvious that more experiments are needed before this conclusion can be accepted as of general significance; but it is certain that slight degrees of myxœdema occurring in the period of involution are liable to be overlooked. I have recently observed and shown a patient³⁰ whose case was perfectly clear on close study, but whose appearance alone would not have attracted notice as abnormal. The case of an elderly gentleman recently described by Dr. F. C. Shattuck, is important in this connection, and not less so for illustrating the liability to the persistence of the ill-effects of thyroid medication, — when such effects occur at all — long after the treatment has been stopped.

THERAPEUTIC ACTION OF OTHER ORGANIC EXTRACTS.

It was impossible that the wonderful discoveries with regard to the effects of thyroid extracts in myx-

œdema should have failed to renew the interest in the use of the other organic extracts (of testicle, brain, spinal cord, etc.) suggested by Brown-Séquard and D'Arsonval,³¹ by Babes,³² and by Althaus.³³

The subject is large enough for a whole evening's discussion, and I cannot pretend to do it justice here. The many observers who have obtained good results from these remedies bring forward an astounding and impressive array of facts in support of their view. Poehl³⁴ shows that similar results may be obtained with his *spermin*, a definite compound obtained from the testicles and the ovaries, and from other glands as well, and adduces evidence that a part of these results are due to increased oxidation occurring under special conditions. It is obvious that all these observations are not to be treated with ridicule, and especially not from an *a priori* standpoint.

What one may and must say, however, is this, that the case for testicoline and cerebrine and myeline in neurasthenia and tabes, and the like, rests on a wholly different basis from that of the case for the use of thyroid in myxœdema. It is not as if we were attempting to cure by injections of spermatic fluid a series of clear and invariable results following castration, though this would be a highly interesting and important experiment. It is a much more difficult matter to decide whether the improvement which takes place in various diseases, even diseases characterized by gross structural changes, like locomotor ataxia, is due to the remedy which has been given.

Explain the fact as we may, the value of all but the clearest therapeutic experiments is enormously vitiated by the fact that mental influences which we cannot gauge are capable of profoundly affecting the result. The powerful phantom of suggestion stands behind the physician's chair, unseen both by him and by the patient, and the influence of the unwelcome intruder is often increased by the very efforts that are made to exorcise him. Althaus, the latest experimenter, recognizes this general fact, but thinks that his observations are free from suspicion on account of the intelligence and mental balance of his patients, and because no attempt was made to impress their imagination. But, the very use of this reasoning indicates a failure to grasp the true significance of the discoveries of the past few years as regards the relation of psychical influences to nutrition. It is not necessary that the patient's imagination should be impressed, in order that results may be produced due to what — for lack of a better name — we must call "suggestion." In hypnotic suggestion the imagination can hardly be said to enter as a factor at all; and even in the many forms of waking suggestion, there is often no conscious stimulation of the imagination. It is, of course, not always easy to say why one drug or treatment should have a markedly greater effect than another; but two causes suggest themselves as often effective. One is the influence of the physician's own feeling of hope or interest, which he may try in vain to conceal,³⁵ and by which the patient may easily be impressed without being himself aware of the fact; the other is the influence of an interest previously stored in the patient's

mind by hearing or reading of the remedy or the method, but perhaps wholly forgotten so far as conscious memory is concerned. The phenomena of "crystal vision," and a host of kindred facts show how potent such "forgotten" cerebral impressions may continue to be. Within certain limits these influences would be all the more active if the patient was intelligent and a person of wide reading and quick instincts of observation.

The admissibility, to say the least, of this explanation of the action of injections of organic extracts is shown by the success which has attended the substitution, under certain precautions, of inert fluids for the testicular or nerve extracts. A large number of control experiments of this sort have been made by other observers,³⁶ and one or two by myself.

One general fact is noteworthy in connection with this branch of the subject, and that is that cures of tabes or locomotor ataxia are perhaps more numerous than any others except neurasthenia. It is, now, well known — in spite of Charcot's "*Quand on guérira le tabes it fera chaud*"³⁷ — that amelioration of some of the symptoms of locomotor ataxia has been brought about, here and there, by several different remedies, such as suspension, injections of phosphate of sodium, and by hypnotism (Moll) as well as by the organic extracts. Moreover, it was noticed long ago, by Westphal and his colleagues, that in cases when the lesions of tabes were combined with those of cerebral degeneration, the ataxia of motion was apt to be much less prominent than where the mental condition was sound. Finally, it is well known that the symptom of pain is pre-eminently susceptible to hypnotic and to waking suggestion; and that persons in a state of somnambulism exhibit an unusual fineness of muscular sense, or sense of position.

It is admissible, I think (though, of course, not obligatory), to read the significance of these facts as follows: that patients with locomotor ataxia are better subjects for psychical treatment than patients with many other analogous forms of disease, because (1) their pain is susceptible of relief in this way, and (2) the aggravation of their ataxia coming from misdirected conscious efforts can be relieved by influences which shunt out the consciousness of their disability in a measure. Perhaps the relief of these symptoms tends also towards a real nutritional improvement in the nerve-centres. Certainly, the reverse is often true, namely, that organic lesions are unfavorably affected by the influence of the symptoms to which they give rise.

Locomotor ataxia seems, again, to be one of those affections where the symptoms may subside in spite of the persistence of the lesions, provided (probably) that the disease is not actually progressing. The important case, with autopsy, by F. Schultze³⁸ published in 1882, affords strong evidence for this view.

My own experience with the testicular and cerebral extracts extended over about a year, during which time I used the injections in a good many cases, but only in nine or ten with a persistence to justify a use of them for clinical inferences. These cases comprise three of locomotor ataxia, and six of what I may call, with sufficient accuracy, neurasthenia. Besides these

³⁸ Quoted by Althaus, loc. cit.

³⁹ Zur Frage v.d. Heilbarkeit der Tabes, Arch. für Psych. u. Neurol., vol. xii, p. 233.

I have the notes of the treatment of a case of chronic myelitis which Dr. Coggeshall kindly allows me to report with the rest. I have also, as a control experiment, treated, for about a month, a case of locomotor ataxia by the injection of a simple mixture of glycerine and water. During part of the time I used testicular fluid obtained from Paris through the kindness of Dr. Brown-Séquard, but the greater part of the extracts were made at the Pasteur Institute of New York. The habitual dose was about two or three grammes. In their most recent publications Brown-Séquard and D'Arsonval advocate a dose larger than this.

The summary of the results of my own experience is as follows: In one of the tabetic cases an apparent improvement was shown, not only in a most gratifying general gain (by relief from pains and increase in strength), but also by the apparent cure of one of the gastric crises. The subsequent history of this patient is, however, very significant. At a later period injections of glycerine and water seemed, also, to help him very much, but after this even testiculine failed to prevent a rapid prostration. Another tabetic patient who was treated with testiculine for about a year, with gain as regards relief of pain and general sense of well-being, was attacked with tubercular laryngitis towards the end of this period, and shortly afterward died. This is noteworthy because Dr. Brown-Séquard has claimed that tuberculosis also is favorably influenced by the remedy. The third patient thought his pain relieved, but there was no marked or permanent improvement in the course of two or three months of treatment.

In Dr. Coggeshall's case of chronic myelitis, the patient received three injections of three to four grammes each, of testiculine, every week, and at the end of seven weeks had gained greatly in every respect. In this case there was a history of syphilitic infection fifteen years before, and the final symptoms were of nine years' duration. Under the injections the improvement began at the end of two weeks. After five weeks of treatment there was a marked gain in power of muscular endurance, a gain of weight of four pounds, an increase of half an inch in the girth of the calves, and of one inch in the girth of the thighs. The grasp, as measured by the dynamometer, increased from 60 to 110. Unfortunately, even while the treatment was still in progress, the patient began to relapse, and had soon gone back nearly or quite to his earlier state.

As an offset to these cases, I will briefly report the case of *tabes* treated by injections of glycerine and water. The patient was a married woman about thirty years old, and there was reason to think that she had been inoculated with syphilis by her husband. The tabetic symptoms, which were of several years' standing, consisted in severe characteristic pains; ataxia of both arms and legs; Argyle-Robertson pupils, with irregularity in outline; loss of the knee-jerk; and impairment of control of the bladder. I had intended to treat her with testicular fluid, and gave one injection for that purpose. At the next visit, however, happening to be out of the fluid, and not wishing to disappoint her, I gave an injection of glycerine and water. At the next visit she was better, and so I thought I would continue the glycerine and water, *experimenti causa*. This is now two months ago, and she has continued steadily to improve in most respects. The ataxia of the hands is no better, but the gait has improved so much that, whereas at first she had to bring

a companion with her, she now comes alone. The pains, also, have left her, and in her general health and feeling there is a distinct gain.²⁰

Of the six neurasthenic patients who remained under treatment long enough to make their histories of value, three were men, three women.

Of the men, one was a gentleman past middle life, eminent for scientific training and powers of observation, who had been for some little time in a nervously debilitated condition, owing to stress of work and other causes. The injections were begun by Brown-Séquard, and continued for a time by me, eventually by himself. The treatment was marked by steady improvement, and ended in complete recovery.

The second case was that of a typically neurasthenic patient, an intelligent physician, rather below middle life, and of good nutrition. The symptoms consisted mainly in an incapacity for application without great mental effort and distress, so that steady work, especially of a literary kind, was well-nigh impossible. Temporary improvement of a very marked sort occurred during the first week of the treatment, and recurred to some extent when the treatment was resumed after an interval of cessation. In the end, however, in spite of thorough and persistent efforts, no permanent benefit was obtained.

With both of these cases one interesting symptom showed itself a few times, when the treatment was first begun, namely, a tendency to erections on the night following the injections. This has been noted also by other observers, but is not regarded as due to the specific character of the fluid, and does not, it would seem, imply that the treatment is especially effective against impotence. In one case of this sort, of purely neurasthenic character, a few injections had no effect.

The third case was that of a young man in a typically neurasthenic state, with morbid fears and marked loss of endurance, due, apparently, to sunstroke. The improvement was steady, but as it had begun before the injections were used, under the influence of encouragement, electricity, etc., and continued after the cessation of the injections at the same rate as before, I did not feel that a large share of the result was to be ascribed to them.

The first of the female cases was that of a young girl with infrequent attacks of epilepsy, and great debility. The improvement during the use of the injections was very great, as regards the debility. The fits were too infrequent to warrant conclusions about them.

The second case was that of a lady past middle life, in a condition of slight mental deterioration of unknown origin. The use of the injections, which were faithfully given for many weeks, afforded her encouragement, but brought no real improvement.

The third patient was a woman with mild hysteria, or neurasthenia with hysteroid symptoms of sensory character. Not many injections were given, but after each one she felt distinctly better. In this case the gain was undoubted, but a similar gain and one equally great followed each of many applications of static electricity, and I was inclined to attribute it in both cases to the encouragement attendant on systematic treatment.

I do not maintain that these few observations are in the least conclusive in either direction; but while it is

²⁰ Some months have passed since this statement was written, but I have not seen the patient this winter, and do not know her later history.

true that all which has been claimed for the organic extracts may have been claimed with justice, yet it should not be forgotten that the claims of hypnotism in similar lines are equally far-reaching, and that what hypnotic suggestion can accomplish it is also possible for waking suggestion to accomplish, under sufficiently favorable conditions.

I will now ask your attention to the consideration of another class of affections associated with diseases of the thyroid, those namely, of which Graves's disease may be taken as an extreme type.

This subject is not yet ripe enough for definite conclusions; and a discussion of the points involved, to be adequate, would necessarily be long. I shall therefore content myself with referring to a few prominent considerations.

In the first place, What is the probable relationship of goitre to the other symptoms of Graves's disease? The following answers, no one of which seem to me wholly satisfactory, have been offered in reply to this question:

(a) Graves's disease is made up of a collection of conditions, part of which are due to the irritation of nerves ramifying in the enlarged thyroid or lying near it, while part are due to an altered thyroid secretion, which acts as a poison. The cardiac symptoms may also be in part explained by disturbance of respiration, as in ordinary goitre.

(b) The whole symptom-complex of Graves's disease is of toxic origin, and due, directly or indirectly, to an increased amount of thyroid secretion or an alteration of its quality.

(c) Thyroid enlargement has no causal relation to the other symptoms of Graves's disease, but like them is due to a disturbance of the nervous system, the exact seat of which is unknown, but which probably consists mainly in a disturbance of some of the functions of the medulla-oblongata.

(d) Finally, the enlargement of the thyroid may be partly a cause, partly a symptom of the Graves's disease complex.

Without attempting to take a positive position in favor of either of these views I will call your attention to a few salient facts.

(1) Quite a large number of cases have now been published in which the partial removal of the enlarged thyroid has led to great improvement and even cure of Graves's disease. I have recently collected fifty-one cases of this sort, in all but a few of which, substantial improvement was obtained by operation. Since I made my collection still others have been reported.⁴⁰ At the same time, the results have not been uniformly good. A case which I have carefully followed was operated on by Dr. J. C. Warren nearly a year ago, and of late even the remnant of the thyroid has nearly disappeared. Nevertheless, the improvement in the patient's condition, though satisfactory in some respects, has not been marked by any permanent change in the exophthalmus or the tachycardia.

(2) Although typical Graves's disease is not common in goitrous districts, yet it is common for patients with ordinary goitre to suffer from some of the symptoms of Graves's disease, especially dyspnoea, palpitation and dysphagia. (Mueller,⁴¹ Maude, Wette,⁴²

Schranz,⁴³ etc.) It is in fact for these symptoms that patients with goitre usually present themselves for operation, and it is not difficult to give a fairly satisfactory explanation (Wette) of the way in which the enlargement of the thyroid might lead to them. The following conditions are often met with: (a) Patients with large thyroids, without other symptoms of any kind; (b) patients with large thyroids and symptoms referable to the respiration and pulse. Occasionally slowing of the pulse is seen (Wette); (c) patients with these symptoms, and in addition, perhaps, exophthalmus and some general nervous disturbance; (d) the same, with the addition and other disturbances frequently met with in connection with Graves's disease.

(3) Some of the symptoms of Graves's disease are occasionally excited by some cause apparently wholly independent of the thyroid. This is true, for example, of exophthalmus, which seems to be sometimes due to disease in the nasal cavity and to sympathetic irritation.

(4) Graves's disease sometimes comes on with great rapidity under emotional excitement, so rapidly that it hardly seems possible that the thyroid secretion should have become increased, although it might have become altered in quality.

(5) There is no good reason for characterizing Graves's disease as a cachexia.

(6) The Graves's disease complex strongly suggests the symptoms met with in conditions of extreme excitement, as in fear or in anger, that is, it occurs as a quasi-physiological complex.

(7) Operations on goitres are sometimes followed by sudden death or by extreme disturbance of the heart and respiration; and no satisfactory explanation for this has yet been given, though several of great interest and importance have been suggested. One that has not been suggested, so far as I know, and which may be worth considering is, that if a large amount of thyroid secretion is poured out from the cut surface of the gland into an open wound it must be rapidly absorbed. Against this view, however, is the fact that these serious symptoms do not always occur.

(8) Improvement may be brought about in cases of Graves's disease by various influences, both general and reflex, tending to quiet a disturbed vascular excitement of the gland or of the heart.

(9) The symptoms of Graves's disease bear a certain resemblance to the nervous symptoms of the first stage of cachexia strumipriva. But this resemblance is not a close one, nor is the contrast which has been suggested as between myxœdema and Graves's disease, more than superficial.

(10) Although the histological characters of the enlarged gland in Graves's disease are altered, and the secretion of colloid is apparently deficient, yet the removal of the greater part of such a gland does not lead to myxœdema.

(11) On the other hand, myxœdema occasionally follows Graves's disease in the same patient, or the two diseases are seen in different members of the same family; and in the same family ordinary goitre may be met with.

We have no right to assume that goitre was the original cause of the symptoms which are cured through its removal.

The recent view that the symptoms of Graves's

⁴⁰ Mainly collected by Möbius (Schmidt's Jahrb., 1893). See also Maude: Lancet, 1893, II; Freiberg: Medical News, August 26, 1893.

⁴¹ Deutsches Arch. für klin. Med., 1893.

⁴² Arch. für klin. Chir., 1892, vol. 44.

⁴³ Ibid., 1886, vol. 24.

disease are due to excess of thyroid secretion, although supported by some evidence, has not been fully established, and is strongly controverted by a recent case in which the disease was cured by sheep thyroid taken by the stomach.⁴⁴

THREE CASES OF SALPINGITIS OF UNUSUAL EXTENT.¹

BY MAURICE H. RICHARDSON, M.D.

- I. DOUBLE PYO-SALPINX OF TUBERCULAR ORIGIN; REMOVAL; RECOVERY.
- II. DOUBLE PYO-SALPINX, PROBABLY TUBERCULAR; REMOVAL; LOCAL PERITONITIS; RECOVERY.
- III. DOUBLE PYO-SALPINX OF SEPTIC ORIGIN; REMOVAL; DEATH.

THE following cases are unusual because of the extraordinary size of the tubes. They are interesting also from their etiology. In the first case the question of diagnosis was a conspicuous feature; the tumors, from their size and apparent solidity, with their intimate connection with the uterus, having deceived every one who examined them. Apparently the growth was a lobulated fibroid. The diagnosis seemed so clear that a sound was not put into the uterus; yet it does not follow that because a uterine sound does not enter an abnormal distance that the uterus is not enlarged. In the second case the diagnosis was easy. The source of the trouble, however, was not so clear. It was impossible to exclude a tubercular element in this case. The possibility of an infection through the uterus was also considered. Whatever may have been the cause in this instance, the great size of the tubes, their outline and their situation made the case one of unusual interest. In the third case a history of a direct infection through the vagina and uterus made the etiology more positive. The methods used and their results justify certain conclusions of value to me in the future management of similar cases.

CASE I. N. Q., aged twenty-four, single. Entered the Massachusetts General Hospital July 5, 1892. There was a family history of consumption. The patient has never been sick. One year ago she began to have pain in the back, which of late has been less severe than at the first. For some time she has noticed a swelling in the lower abdomen on the right side. Of late the pains have been referred to the thighs and have been sharp and shooting. Catamenia regular until last month, when they were absent. She had always had dysmenorrhœa. There has been a slight vaginal discharge. She has lost thirty pounds in weight in the last year. Her appetite is good. Urine normal. She is not confined to the bed.

Below the umbilicus the abdomen was enlarged, and contained a mass about the size of a six months' fetus, with two prominent tumors. The mass of both tumors was somewhat to the right of the median line and was slightly tender and movable. The uterus moved with the movements of the tumor. The uterine sound was not passed. A large mass could be felt in the posterior cul-de-sac. She was examined by several of the staff, and the diagnosis of a uterine fibroid was made. This case was carefully studied until the 15th of July, when a median laparotomy was performed. As soon as the abdominal pressure was

relieved by delivery of the tumors, both stood upright in the wound, presenting the very extraordinary appearance of two convoluted masses, perfectly symmetrical, attached one to each cornu of the uterus, like enormous spiral horns. Both tumors extended deep into the pelvis and were attached by adhesions so easily separated that the continuity of the tubal wall was not broken. The peritoneum was studded with miliary tubercles; — tubercular salpingitis was evident. The patient made an uninterrupted recovery. A small portion of the omentum was removed for microscopic examination.

Dr. Mallory's report is as follows: Nodules miliary tubercles. The tubes are eighteen and nineteen centimetres in length, circumference twenty-four centimetres each, weight *one and one-half pounds each*. Thin walls filled with thin, greenish-yellow pus; peritoneal surface studded with gray miliary tubercles.

The patient came to the hospital to have this operation performed so that she could get married. I dare say that she has carried out this intention. This case is an extraordinary one from the great size of the tumors, and is interesting from the difficulty met with in diagnosis and from the glaring error made by every one. The necessity for the operation was apparent, even with the incorrect diagnosis of fibroid. The shape of the tumors was characteristic of the large dilatations of the Fallopian tubes. The great lengthening of the tube which accompanies the increase in lumen gives a spiral shape to the tumor. This appearance was well marked in the other cases. As a rule the distal end of the tube becomes rounded and projects into the pelvis, where it becomes adherent. In the present instance the enormous double enlargement was so great that the pelvis could not hold the mass. The tumors were not so deeply attached and firmly adherent as in Cases II and III. Separation was therefore accomplished so easily that no fluid escaped.

CASE II. Massachusetts General Hospital, August 26, 1893. Eunice G., aged twenty-six, married five years ago, has always been well. One miscarriage four years ago. Catamenia have been irregular, several periods having been missed without pregnancy. Four years ago, after being sick in bed with pain in the right side, the doctor lanced an abscess in the vagina. A year later a lump was noticed in the right side of the pelvis which has lasted ever since. Two weeks before entrance, she was taken with chills, fever and great general tenderness.

General condition poor; facies "peritoneal" and anxious. Marked swelling in the lower abdomen over right tube, with increased resistance and ill-defined dulness. Great tenderness at this point; whole abdomen somewhat tender. Constitutional symptoms severe. By vagina a bulging mass was felt on both sides of the uterus, which was firmly fixed in the centre.

The question of supra-pubic operation presented itself. The fluctuating tumor felt by the vagina invited drainage in that direction; but the unsatisfactory results that follow vaginal and rectal drainage in pelvic abscesses; the brilliant recoveries which take place after abdominal section, with the immobility and sharp definition of the tumor that presented in the abdomen, decided me to take the abdominal route.

In the extensive tubal disease found in this case abdominal section is much better than vaginal drainage, in my experience. Recovery is much more rapid and

¹ Read before the Obstetrical Society of Boston, December 9, 1893.

⁴⁴ Owen: British Medical Journal, 1893, II, p. 1211.

complete. Moreover the mortality is no greater, considering the complications that may attend the prolonged convalescence of the latter method, the insufficiency of the drainage at times, and the not infrequent involvement of the bladder. To have seen a few women slowly waste away and die after the failure of rectal and vaginal incisions, to have seen the greatly increased dangers and difficulties of the abdominal operation after the failure of the vaginal, to have watched the progress of intestinal, vesical and other fistulæ — to have seen a few of these deplorable conditions, makes one hesitate in adopting the so-called safe operation of dependent (always septic) drainage. Not that vaginal drainage should never be employed. It can do no harm when an abscess is clearly pointing, for, by the supra-pubic, rectum drainage will have to be established, and probably vaginal also. But in conditions in which complete extirpation of the dilated tubes and their contents is possible, there is no argument of weight in favor of the vaginal, much less the rectal incision.

On the 28th of August a median incision was made, with the patient in the Trendelenberg posture. The abdominal cavity was thoroughly protected from possible extravasations by means of gauze barriers. The right tube was found to be as large as two fists, and everywhere adherent. The whole tumor was freed from its adhesions and delivered from the abdominal wound. The uterine attachment was tied close to the uterus. On the left side, also, a tumor was found — not quite so large as the one in the right. In freeing the adhesions on this side the abscess was ruptured, and at least four ounces of what seemed to be pus escaped. In spite of every precaution, the intestines were somewhat contaminated by this fluid. The tube was delivered and tied near the uterus with silk. The contents of this tumor, like that of the right, seemed to be purulent. It was greenish-yellow and odorless, thick and tenacious. The intestines that presented were carefully wiped with sterile gauze; the abdominal wound was closed without drainage.

The patient's temperature rapidly fell to the normal line, and she improved very much. In the course of a few weeks, however, she began to get hectic. A mass could be felt both by vaginal and by abdominal palpation. I was on the point of incising the posterior cul-de-sac several times. Finally, however, there was an abundant discharge of pus with a small piece of gauze from the rectum. Through this spontaneous opening the finger could be introduced into an abscess cavity situated behind the uterus. The convalescence from this time was steady, and she is now in excellent condition.

The dangers by the intra-abdominal method of treatment in cases of this kind may be very great. Safety to the patient depends upon causes beyond the control of the surgeon, if he selects this route. It is beyond human skill in many cases of this kind — in which the tubes are enormously dilated and presumably adherent, to remove the tumor without rupturing it. Notwithstanding all precautions, the extravasated fluid will contaminate the peritoneum more or less on all sides. In spite of irrigation, of wiping out with gauze, of thorough disinfection — of every thing that we can do in those instances in which the fluid contains the more septic micro-organisms — the dangers of a general and fatal peritonitis are very great. In this case, the abdominal wound was closed. We knew nothing

as to the septic or aseptic qualities of the fluid when the peritoneal cavity was sealed. We were very fortunate, therefore, that there was not a general septic peritonitis and death. The accidental presence of the gauze would have had nothing to do with the sepsis in the absence of a septic element pre-existing in the fluid, for I have often left gauze-padding much longer than this without symptoms. Unless we can demonstrate on the spot, by some of the rapid methods of staining micro-organisms, the absence of these bodies, we have no right at present to close the abdominal wound. We must give the patient the benefit of the doubt, and provide for drainage in every instance. Not that drainage is sure to prevent a general septic infection — it will not do this invariably; but if by means of tubes or of gauze, or of both, the toxic products of germs can be removed as fast as they form, the prospect of recovery is much better.

CASE III. Sarah H., aged forty-five. Boston. Admitted to the hospital October 1, 1893. Menstruation regular, slightly painful, not profuse, for thirteen years. Married twenty-seven years ago. No children. Second marriage four years ago. No children. Pregnant once at nineteen, and some sharp instrument was used to produce abortion. Has never been free from pelvic trouble since. During the last twelve years has had various disorders — pneumonia, congestion of the lungs, nervous prostration, etc. Last summer a tumor was discovered in the left ovarian region. Six weeks before entrance to the hospital, while doing her housework, during her catamenia, pain to which she had been subject off and on for years, became worse than usual, and she had to go to bed. In the course of two days an ulcer broke in the womb, and thick, greenish matter escaped. Has been in bed ever since. There have been severe spells of vomiting, lasting a day at a time. Micturition has been frequent and difficult. Yesterday and to-day has had chills and fever for the first time.

Face pale and pasty; valvular disease of the heart; abdomen very fat, and somewhat tender all over, especially above pubes and to the left, where a round mass about the size of two fists or larger, dull on percussion, could be indistinctly felt. In addition to the tumor on the left, another could be felt less distinctly on the right; both were fluctuating, and seemed unattached to the abdominal wall.

At my first examination (without ether) it seemed to me that the operation would consist simply in incision and drainage, either through the abdominal parietes, to which the tumor on the left seemed then adherent, or through the vagina, or by both routes. As soon as the patient was etherized, however, the unattached condition of the tumor on the left and the presence of another on the right could be clearly demonstrated. I therefore made the median incision, the patient having been prepared for laparotomy. The right tube was enlarged to about the size of two fists, or a little smaller; it was adherent deep in the pelvis, but not attached anteriorly. The adhesions were separated carefully, and the whole mass was delivered without rupture. A ligature was applied close to the uterus; and the whole tumor removed. There was no escape of fluid during this procedure. The left tumor, which was considerably larger than the right, was next isolated, as far as possible, by separating the recent adhesions. The undelivered extremity of the tube, pointing downwards and forwards to the left

of Douglas pouch, was so intimately adherent in the depths of the pelvis, that I found it impossible to separate the mass without rupture. There was a very large escape of foul fluid, apparently pus, which contaminated everything in the vicinity. All the intestines and the lower part of the abdomen were bathed in this fluid, in spite of all efforts, either by the interposition of gauze barriers or by rapid irrigation. The pelvis was cleaned as carefully as possible, by the use of both boiled water and sterile gauze. A small gauze drain was placed in the pelvis, and the incision was closed with silkworm-gut sutures. The operation was a very rapid one, but the amount of shock following was considerable. Her condition, however, which even before the operation was very serious, slowly improved. There was no vomiting.

On the following day there was moderate staining from the drain. The temperature and pulse steadily rose. Salines were given in drachm doses every hour. On Monday, the 9th, the bowels moved freely. Large quantities of gas also were passed. Her condition was very poor, and steadily getting worse. There was no pain in the abdomen — which was distended — and no vomiting. Her general condition was very bad. During the day she gradually failed, and died early on Tuesday morning.

This operation differed in no respect from that in the preceding case, except in that the patient soon showed evidences of septic absorption. Though a general peritonitis did not develop, yet there was sufficient poison in the localized peritonitis that did follow to produce a fatal septicæmia. An examination of the fluid showed the presence of the streptococcus pyogenes, with some of the less virulent micrococci.

This case shows the importance of early operation in some forms of salpingitis. While in the first case the symptoms were in no way so severe as would be expected in tubercular abscess, yet in the second there were more or less serious constitutional disturbances. But even in the second case there were no elements present which were likely to produce serious local or constitutional disturbance. In the third case, on the contrary, there was a mass of fluid likely at any moment to break into the peritoneal cavity, and so virulent in its micro-organisms that death followed in less than three days, through the local infection alone. Her extreme prostration undoubtedly opposed but feeble barriers to the septicæmia, and death in spite of free catharsis was probably due to a very moderate absorption.

It is an interesting question to differentiate these conditions, and it does not seem especially difficult to do so in the later stages. Unfortunately, in delayed cases, the prognosis is much more serious. It does not seem reasonable to allow tumors of the Fallopian tubes to attain such a size as these specimens show — no matter what the cause of the process may be. The operations for the removal of tumors may not be especially hard. They may present, of course, great difficulties; — their removal may even give rise to some of the gravest emergencies in surgical procedures. But the chief danger in the late operation lies in rupture of the dilated tube with unavoidable peritoneal infection. Though in none of the above cases were the adhesions impossible of separation, yet the tumor might have been so intimately attached that enucleation would have been out of the question. Not infrequently the bowel has been torn open in

forcible attempts at separation. In early extirpations, most of the above dangers are avoided.

These cases certainly indicate a much earlier operation in salpingitis than was performed. If we can demonstrate, by bimanual palpation, the existence of tubal inflammation so extensive that there is no reasonable hope of cure, either by natural processes or by drainage through the uterus, then we ought to interfere surgically in every case in which there is no contra-indication in the condition of other viscera. Not only by the experience gained in these cases, but also by that met with in much less extensive forms of salpingitis, am I inclined to favor early interference when the tubes are distinctly diseased. I would not advocate so severe an operation as an abdominal section, however, unless the progress of the disease was distinctly unfavorable; unless the local evidence was marked; and unless, under palliative treatment, there was no distinct progress toward permanent disability. The results in my operations for this disease have all been, almost without exception, very gratifying when recovery has followed. In the third case reported, and in another similar one drained some years ago by abdominal section, death took place. All the others recovered. The number is not great, — probably not over fifteen or twenty. I would not be willing to say that the mortality is nil; still in cases that have not advanced to any great degree of local or general infection, I regard it as so inconsiderable that the outlook — not only for immediate, but for permanent cure — is very gratifying.

The prognosis in uncomplicated cases in which the tubes are not greatly enlarged and can be tied and removed without infecting the peritoneum, is very much like that after removing the appendix in the interval between attacks. The operation is very similar, and the danger of hæmorrhage or infection not unlike.

In all cases of pyo-salpinx, as well as in all cases of suppuration elsewhere in the abdominal cavity, excessive care is necessary in the evacuation of pus, or of what seems to be pus. In many instances the fluid contained in the Fallopian tube is sterile, but it is clearly impossible by the naked eye to tell whether a given fluid is septic or not. Our technique must be so carried out that all contamination shall be avoided as far as possible. In hospital as well as in private practice, it is extremely desirable to have slide preparations examined on the spot by an experienced bacteriologist, while the process of cleansing the abdominal cavity is going on; for the method of treating the wound depends upon the results of such examination. If no pathogenic bacteria can be found by such a method of rapid staining, for example, as that just described in the JOURNAL of December 7th by Mr. Barney, irrigation may be dispensed with and the abdominal wound may safely be closed. If, on the other hand, the streptococcus or other pathogenic micrococci are present, or the fatal colon bacillus, we should make renewed efforts at cleansing and disinfection; we must not, under these circumstances, close the abdominal wound without providing free drainage, by the use of either gauze or a tube, or both.

PHILADELPHIA ADVERTISING. — A Philadelphia firm of truss-makers has sent out a circular to physicians offering commission in the following bold manner: "If you will send us your patients, we will reciprocate with a check by return mail."

A BACTERIOLOGICAL STUDY OF FOUR HUNDRED CASES OF INFLAMMATION OF THE THROAT, OCCURRING IN DIPHTHERIA AND SCARLET FEVER, WITH ESPECIAL REFERENCE TO PATHOGENESIS.¹

BY JOHN LOVETT MORSE, A.M., M.D.

WE owe the first description of diphtheria to Bretonneau. He regarded the presence of a pseudo-membrane in the pharynx and upper air-passages as its characteristic feature. The infectious nature of the disease was first recognized in 1860 by Trousseau, who considered the local manifestations as comparatively unimportant. As the disease became more prevalent, more and more attention was directed to its clinical characteristics, and the presence of a pseudo-membrane in the throat was again regarded as its diagnostic feature. It was noted, however, that the membrane varied in different cases. In some it was removed with difficulty and left a raw, bleeding surface; in others it proved to be a mere exudation, and left an intact surface after its removal. It was also found that a fibrinous exudation, taking the form of a membrane, anatomically indistinguishable from that found in diphtheria, could be produced in a number of ways, as by wounds and irritants of various sorts. This same pseudo-membrane was also found to be produced in other portions of the body by the same irritants. A pseudo-membrane was also noted in scarlet fever, measles and typhoid fever. The discovery of these facts resulted in great confusion and accurate diagnosis was impossible. Every man had his own standard and no one could prove whether he was right or wrong.

Much of the confusion arose from the fact that men failed to recognize that a diphtheritic inflammation is essentially an anatomical process and does not necessarily have any connection with the infectious disease, diphtheria. Any inflammation characterized by a fibrinous exudation forming a membrane on the inflamed surface is a diphtheritic inflammation, however it may be caused. The diphtheritic membrane is due to a combination of necrosis and inflammation with fibrinous exudation. The essential factor is a necrosis of the surface epithelium. This necrotic tissue supplies the fibrin ferment, and fibrin is formed from the serous exudation which comes in contact with the necrotic tissue. The membrane itself is found on microscopical examination to consist almost entirely of fibrin and of necrotic tissue which has undergone fibrinoid metamorphosis. The tissue beneath shows evidence of the most intense inflammation. It is infiltrated with inflammatory exudation, the blood-vessels are dilated and pus cells are found in the vessels and in the tissue. The necrosis is not limited to the surface but extends irregularly into the tissue below, often passing beneath the unchanged epithelial surface. It is here also accompanied by the formation of fibrin, the fibrin in the tissue below often connecting with that on the surface, causing this to adhere more strongly. Confusion has also arisen from the so-called diphtheroid affections of the throat. In these inflammations we may have masses of detritus, consisting of cast-off epithelium, mucus and masses of bacteria, collected on the surface of the mucous membrane and frequently extending

into the follicles. These masses can be removed in more or less adherent flakes. Under the microscope they are often found to be composed almost entirely of mucus, epithelial and pus cells, and bacteria of various forms, which evidently find a favorable culture medium in the collections of mucus and cast-off epithelium. These deposits are sometimes accompanied by marked signs of local inflammation as well as by constitutional disturbance, due to the absorption of chemical products.

The discovery of bacteria and their relation to disease, however, offered a solution for the problem. After years of careful investigation by many observers the bacillus causing the disease was isolated and its pathognomonic character demonstrated. Klebs (1) in 1883 found that a bacillus, always the same morphologically, was constantly present in the pseudo-membrane of cases of epidemic diphtheria. Löffler (2) in 1884 investigated the subject still further and found that this bacillus was pathogenic in certain animals, and produced, on inoculation, a pseudo-membrane on the surface inoculated. The whole subject has been carefully gone over by numerous investigators since that time, notably Löffler, Roux and Yersin (27), Babes (3), Welsh and Abbott (4). Pseudo-membranes, paralyzes and organic lesions, similar to those in man, have been produced in animals by inoculation and a toxine has been isolated, which produces, when inoculated, the same results as the pure culture, with the exception of the pseudo-membrane (5, 6, 7). This toxine is probably due to a ferment produced in the membranes by the bacillus, which is absorbed and forms poisonous albumins and an organic acid in the body (7, 8). Hence we now consider only those pseudo-membranous inflammations as diphtheria, in which this bacillus, known as the Klebs-Löffler, is found. Therefore, no diagnosis can be made, which can be regarded as more than probable, without the bacteriological demonstration of this bacillus.

The Klebs-Löffler bacillus is a small organism not much larger than the tubercle bacillus. Its most striking feature, morphologically, is its variation in form and its irregularity in staining. The ends of the organism are frequently clubbed, sometimes one and sometimes both ends, and in most cases when stained it shows a series of clear spaces along with intensely stained particles. The form and size vary greatly under various circumstances. In different cases it appears in some much larger and more irregular than in others, and in the same preparation great irregularity may be seen. It grows readily on a variety of culture media and most readily on the modified blood serum first introduced by Löffler. When cultivated on potato it is much larger and more irregular in form than when grown on any other medium. The organism is pathogenic for a number of animals, especially for young cats and guinea-pigs. In guinea-pigs the most virulent form of the organism will produce death in from thirty-six to forty-eight hours. Like some other organisms, there is a marked difference in its virulence. While cultures from some cases will always produce death in thirty-six hours, in others death will not take place for several days; and in others, again, the animals may survive the primary inoculation, and afterwards die of paralysis after an interval of three or four days. Again, in still other cases, no results may follow the inoculation (9).

Numerous cases of pseudo-membranous inflamma-

¹ A contribution, under direction of Dr. W. T. Councilman, from the Pathological Department to the forthcoming Medical and Surgical Report of the Boston City Hospital. Awarded one of the Lyman prizes for 1893.

tion of the throat are met with, however, which are due to other bacteria than the Klebs-Löffler bacillus. These cases are absolutely indistinguishable clinically from those due to the action of the Klebs-Löffler bacillus, and may be precisely the same anatomically. As a rule they are associated with streptococci, as is notably the case in scarlet fever and measles. Moreover, the Klebs-Löffler bacillus and the streptococcus are often found together or accompanied by staphylococci and other organisms. A differential diagnosis is only possible by a careful bacteriological examination. The utility of clinical conclusions has been shown by numerous investigators. In 1889, Prudden (10) investigated twenty-four fatal cases which had been diagnosed clinically as diphtheria. In several of these cases scarlet fever and measles were also found. The Klebs-Löffler bacillus was not found in one, but the streptococcus in all but two. Baginsky (11), in one hundred and fifty-four cases diagnosed clinically as diphtheria found the Klebs-Löffler absent in thirty-four. Martin (12), in two hundred suspected cases of diphtheria found no Klebs-Löffler in seventy-four. Park (13), in one hundred and fifty-nine cases of pseudo-membranous inflammation, found the diphtheritic bacillus in only fifty-four. In every one of the remainder streptococci were the most abundant bacteria, and often the only ones. Koplick (14) found the streptococcus alone in eleven cases of clinically pure fibrinous diphtheria. Janson (28), in one hundred cases of pseudo-membranous angina, met with the Klebs-Löffler bacillus in only sixty-three.

As the prognosis, contagiousness, and hence the necessity for isolation, varies greatly with the form of bacteria present, the necessity of an accurate and early diagnosis is evident. This can only be obtained bacteriologically. By the examination of a cover-slip preparation, prepared directly from the throat, the presence of the diphtheritic bacillus may often be demonstrated immediately. This method is fortunately most valuable early in the disease (29) (15). The presence of the bacilli is positive evidence, their absence only negative, and in these cases further examination by means of cultures is necessary. In fact, it is advisable to examine all cases by cultures as well, which requires only twenty-four hours for the determination of the presence of the bacteria.

The main objects of my work have been to determine by the examination of a large number of cases, in which diphtheria had been diagnosed clinically, or at least strongly suspected: (a) the proportion in which the Klebs-Löffler bacillus was present; (b) whether or not, and if so, in what way, the prognosis was altered by its presence; (c) in what way the prognosis was altered by the presence of other organisms in combination with the Klebs-Löffler bacillus; (d) what these organisms were and how often they were found. During the course of my investigations many other points have come up which seem worthy of special note, particularly the results bearing on the length of time which the bacillus remains in the throat and nose after convalescence is established.

The method employed was essentially the same in all cases. Swabs are made by winding absorbent cotton tightly on the end of a piece of stiff wire five inches long. These are put in cotton stoppered test-tubes, and sterilized by dry heat. The swab is rubbed thoroughly over the throat, and put back in the test-tube. In the laboratory the swab is carefully rubbed

over the surface of a slant tube of Löffler's blood serum mixture. A platinum loop is run over the surface of this tube, and then smeared on a second tube; this procedure is repeated on a third tube. The cultures are left in the thermostat at a temperature of 35° C. until the next day and then examined microscopically. The colonies on the third tube are usually discrete enough to admit of a differential diagnosis of the organisms present. The diagnosis has been made, as a rule, on morphological appearances, although in many cases the cultural peculiarities have been investigated and animals inoculated. In one series of twenty-five cases, which will be given in detail later, the various organisms were isolated in pure cultures and accurately differentiated on the various media. The blood serum was prepared according to Löffler's well-known formula, solidified slowly in the dry sterilizer at 75°-80° C., and then sterilized in Arnold steam sterilizer at 100° for one-half hour on three successive days. This method is much simpler than the one in ordinary use, saves all the media, and is entirely satisfactory in every way. The organisms grow as rapidly and as vigorously as on blood serum prepared by the old method. The time and trouble saved in this way is evident. Löffler's methylene blue solution was ordinarily employed in staining. Four hundred cases have been investigated in this routine way. All of them were examined after admission to the diphtheria ward of the City Hospital, or were cases in the scarlet fever ward whose throats were suspicious.

These cases, as a rule, come from the tenement-house districts in the thickly-populated portions of the city, the North End, about Dover Street, and South Boston. A few, however, come from the outlying districts, as Brighton and Roxbury. It is safe to say that a very large portion of them live in improper hygienic surroundings, and are in poor condition to resist so severe a disease as diphtheria. Moreover, many are not brought to the hospital until they are *in extremis*, and die within the first twenty-four hours. The proportion of adults is very small, only seventeen per cent. of the present series being over fifteen. All these factors have an important influence on the statistics and make the percentage of mortality appear far worse than it would in other circumstances.

DIPHTHERIA, SCARLET FEVER.

The presence of the Klebs-Löffler bacillus was demonstrated in two hundred and thirty-nine, that is, in sixty per cent. of all suspicious cases. There were three hundred and one cases in which scarlet fever was not present, not excluding, however, those cases in which it may have occurred earlier or later. Of these, the Klebs-Löffler bacillus was present in two hundred and seventeen, or seventy-two per cent. These results correspond pretty closely to those obtained by other investigators, Baginsky (1) having found the Klebs-Löffler bacillus in one hundred and twenty cases out of one hundred and fifty-four, or seventy-eight per cent.; Martin (12), in one hundred and twenty-six out of two hundred, or sixty-three per cent.; Park (13), in fifty-four out of one hundred and fifty-nine, or thirty-four per cent.; and Janson (28), in sixty-three out of one hundred, or sixty-three per cent.

One hundred and thirty-six of the four hundred cases examined died, giving a general mortality of thirty-four per cent. Of the two hundred and thirty-nine cases containing the Klebs-Löffler bacillus ninety-nine

died, that is, forty-one per cent. Of the one hundred and sixty-one in which it was not present, thirty-seven died, or twenty-three per cent. The general mortality of the three hundred and one cases not complicated with scarlet fever was thirty-six per cent. Eighty-nine of the two hundred and seventeen cases in which the Klebs-Löffler bacillus was present, died, that is, forty-one per cent.; in the eighty-four in which it was absent, twenty-one, or twenty-five per cent. died. Of the remaining ninety-nine cases in which the diagnosis of scarlet fever or scarlet fever and diphtheria was made, twenty-six, or twenty-six per cent. died. The Klebs-Löffler bacillus was demonstrated in twenty-three, ten of which died, or forty-three per cent. Of the seventy-six cases in which it was absent, only sixteen, or twenty-one per cent. died.

Mortality in four hundred cases	34%
" in all cases containing K. L.	41
" in all cases without K. L.	23
" in all cases uncomplicated by scarlet fever	36
" in these cases which contained K. L.	41
" in these cases which did not contain K. L.	25
" in all cases complicated by scarlet fever	36
" in these cases containing K. L.	43
" in these cases not containing K. L.	21

These figures go to prove that the mortality in pseudo-membraneous inflammations of the throat is nearly twice as great in those in which the Klebs-Löffler bacillus is present as it is in those in which it is absent. Somewhat similar results have been obtained by other observers. Park (13) records a mortality of forty-six and one-half per cent. in true diphtheria. Twenty-five per cent. of Janson's (28) series, in which the Klebs-Löffler was found, died, while all the other cases of angina, uncomplicated with scarlet fever, recovered. In Baginsky's (11) series, thirty-eight per cent. of those with Klebs-Löffler died, compared with eleven per cent. of those without. Heubner (15) found a mortality of sixty per cent. in seventy-seven cases of true diphtheria.

Of the sixty-two adults, Klebs-Löffler was present in thirty-eight, absent in twenty-four. The general mortality was nine per cent.; that of those in which the Klebs-Löffler bacillus was present, thirteen per cent.; of those in which it was absent, four per cent.

MEASLES, SCARLET FEVER.

A mild epidemic of measles occurred in the scarlet-fever ward during the course of this investigation. Six cases had measles and scarlet fever together. All recovered, and the Klebs-Löffler bacillus was not found in any. Streptococci were present in five; staphylococci in two, and the diplococcus lanceolatus in three. Four cases of measles with severe throat symptoms, giving rise to the clinical diagnosis of diphtheria, occurred. One contained a few Klebs-Löffler bacilli and many staphylococci and recovered. The others were practically pure cultures of staphylococci, and all died, one, however, of scarlet fever contracted while convalescent. These cases, as far as they go, show that the Klebs-Löffler bacillus is certainly a very rare accompaniment of the throat complications of measles. The literature on this point is very scanty. Hofmann (16) and Escherich (17) claim to have found the pseudo-diphtheritic bacillus in several cases of measles.

TYPHOID FEVER.

Four cases of typhoid fever with throat complica-

tions have been examined, and seem worthy of separate consideration.

L. F., for some time a patient on the surgical side, developed a sore throat. Bacteriological examination showed a few Klebs-Löffler bacilli. She was transferred to the diphtheria ward, where a few days later the diagnosis of typhoid fever was made. She ultimately recovered. A guinea-pig, inoculated with a pure culture of the Klebs-Löffler bacillus obtained from her throat, died.

K. W. entered the hospital after a sickness of a week. The diagnosis of typhoid was made, but she was put in the diphtheria ward because of her throat. Examination showed a few Klebs-Löffler bacilli, many staphylococci, and a few streptococci. Her throat was clear in five days, and she was soon after transferred to a medical ward, where she recovered.

F. D. was ill with typhoid in a private room. A nurse, several days after leaving the scarlet-fever ward, had a sore throat, and was put in the same room over night. On the discovery of the Klebs-Löffler bacillus on the next day she was transferred to the diphtheria ward. Four days later F. D. developed a sore throat with membrane. The presence of the Klebs-Löffler bacillus was demonstrated, and she was also transferred. The next day a typical scarlet-fever rash developed, which was followed by desquamation. Her throat was clean in ten days, and she ultimately recovered.

Isabella N., nineteen, was admitted to the medical wards of the Boston City Hospital on October 27th, at about the middle of the first week of typhoid. She was a large, well-built girl, in very good condition. A faint systolic murmur was noted in the heart at both base and apex. Although her temperature ranged high, she did very well until November 4th, when she became delirious and her pulse more frequent. She slowly lost ground, and on November 11th it was noticed that swallowing was painful. Examination of the throat showed both tonsils and pillars of fauces covered with a dirty-white membrane, which extended all over adjoining parts of soft palate and uvula. The posterior pharyngeal wall was not seen. She was immediately transferred to the diphtheria ward. Cultures from swabs made on this day and the next showed streptococci and staphylococci, but no diphtheria bacilli. Blood-serum tubes made from swabs of November 14th showed almost pure cultures of the Klebs-Löffler bacillus. She was able to take but little nourishment, and remained semi-unconscious and delirious. Her pulse gradually failed, and she died on November 17th. Her throat had begun to clear up during the last two days. The autopsy was performed by Dr. Councilman thirty hours after death.

Body. — Large, well-built, tolerably well-nourished.

Skin. — Generally pale and anæmic. Mucous membranes pale. Posterior surface of body slightly congested. No eruption. Subcutaneous fat medium in amount.

Abdomen. — Moist and peritoneum smooth, save over spleen, where there is a slight fibrinous exudation. Both liver and spleen free from connective-tissue adhesions. Along course of ileum and colon areas of congestion. Diaphragm in usual position. Anterior mediastinal glands slightly enlarged and reddened.

Lungs. — Remarkably free from pigment. Both slightly adherent by old adhesions. The entire posterior part of right lung congested, oedematous, and slightly consolidated, the consolidation generally lax,

with here and there areas of more distinct consolidation about the bronchi. The entire pleural surface of this portion of the lung covered with a slight fibrinous exudation, more marked between the lobes. The parietal pleura congested. Abundant muco-purulent secretion from the bronchi everywhere in the lungs, particularly in the posterior parts. In the left lung there are a few areas of consolidation about the bronchi, but the consolidation is everywhere less well-marked than in the right. The bronchial glands distinctly enlarged, reddened, and slightly pigmented.

Heart. — Medium size. Both layers of pericardium smooth. The myocardium generally pale without any appearance of faded leaf. In the right ventricle there are fresh clots. In the left there are old thrombi covered with adherent fresh clots along the musculæ trabeculæ of the septum and the apex of the ventricle.

Liver. — Large. Surface pale, markings somewhat obscure. Gall-bladder distended, bile-ducts free. On section, liver pale and somewhat cloudy.

Spleen. — Seventeen by ten by five centimetres. Weight three hundred and forty grammes. Surface covered with a slight fibrinous exudation. On section, comparatively firm, homogeneous, of a dark-red color, small dark-red points of hæmorrhage scattered through it. Neither Malpighian bodies nor trabeculæ visible.

Kidneys. — Of ordinary size. Surface smooth and capsule not adherent. The lobules very evident. On section, cortex pale, markings faintly visible, the labyrinth cloudy. On the surface of the right kidney there is a slightly elevated, soft, nodular mass, one and a half centimetres in diameter. On section the cortex at this point is soft, pale, with opaque white streaks and points scattered through it; where it extends into the pyramid, it has a reddish color.

Mesenteric Glands. — Both of the mesentery and mesocolon are enlarged, deeply injected, and soft. The post-mesenteric are also enlarged and reddened.

Intestines. — In the intestines there are numerous ulcers. There is one low down, almost in the rectum. Throughout the large intestine there are numerous ulcers with sharply circumscribed edges and perfectly clean base, extending down to the muscular coat, one of them extending through this to the peritoneum. In the small intestine also there are ulcers of the same general character as those in the large. Higher up in the intestine are some with sloughs in the base.

Adrenal Glands and Pancreas. — Normal. The pancreas large and firm.

Pharynx and Larynx. — Mucous membrane of the pharynx covered with an extensive muco-purulent mass. The tonsil on left somewhat enlarged and covered with a whitish deposit, which is easily scraped away, but does not wash off. On removal of this there is an epithelial loss of substance. There is an extensive formation of the same substance on the lateral wall of the pharynx opposite to the larynx. In the larynx there is an irregular ulcer on each side along the posterior portion of the vocal cord. The edges of the ulcer have a grayish film over them; the base also. All of the cervical glands are enlarged, softened, and reddened. The trachea is intensely congested.

ANATOMICAL DIAGNOSIS.

Typhoid Fever. — Ulceration of ileum and colon.

Diphtheria.

Heart thrombus.

Renal Infarction.

Congestion, œdema, pneumonia, and bronchitis in the lungs.

Acute swelling of spleen.

Diphtheritic ulceration of larynx.

Diphtheritic pseudo-membranous inflammation of pharynx.

Hyperplasia of lymphatic glands.

Acute parenchymatous degeneration of liver, kidneys and heart.

BACTERIOLOGICAL EXAMINATION.

Lung. — Pure culture streptococci.

Tonsil. — Numerous streptococci and other cocci, with a few Klebs-Löffler bacilli.

Trachea. — Mainly streptococci and Klebs-Löffler bacilli.

Tracheal Gland. — Negative.

Bile. — Typhoid bacilli.

Spleen. — Typhoid bacilli.

Mesenteric Glands. — Bacillus coli communis.

Pleura. — Streptococci.

Bronchial Glands. — Streptococci.

Heart's Blood. — Negative.

Heart's Thrombi. — Typhoid bacillus; streptococci.

Kidney Infarction. — Typhoid bacilli; streptococci.

Kidney. — Typhoid bacilli; streptococci.

Liver. — Streptococci.

One of the two pigs inoculated with the pure culture of the Klebs-Löffler bacillus, obtained from the trachea, died in forty-eight hours with the pathological lesions of experimental diphtheria. The bacilli, however, were not found at the seat of inoculation. As far as I know this is the first reported autopsy of a mixed case of typhoid and diphtheria. It proves conclusively that certain of the inflammations of the throat occurring in typhoid may be due to a mixed infection with the Klebs-Löffler bacillus. The other cases cannot be considered as more than suggestive. Wagner, who has given the most accurate description of the angina accompanying typhoid fever, calls attention to the greater frequency of pseudo-membranous affections when diphtheria is prevalent.

The bacteriological examination of the tissues of the case show that three different infections have taken place. One by means of the typhoid bacillus; one by means of the Klebs-Löffler, and one by a streptococcus, which probably found its point of entrance in the tissues from the lesions in the throat. Evidences of these three different infections were present in the tissues. The general lymphatic hyperplasia was due both to the typhoid and diphtheria. The lesions in the lung and pleura were due to streptococci coming from the throat, and from here the general infection of the body may have taken place. Streptococci were found in the thrombus in the left side of the heart, and on section of the tissue beneath the thrombus there was a slight endocarditis with streptococci in the superficial layers of the tissues. The embolus which produced the infection of the kidney came from the heart thrombus and produced a circumscribed purulent infiltration of the kidney in the place of a simple infarction. No effect seems to have been produced on the intestinal ulcers by the other infections. They had the typical appearance of late ulcers in the beginning of healing. The presence of the streptococci in the acute fibrinous pleurisy shows that they may produce in the pleura as typical a fibrinous exudation as is found in the pleurisy accompanying an acute croupous pneumonia.

(To be continued.)

Clinical Department.

A CASE OF ACUTE INFECTION SIMULATING ACUTE YELLOW ATROPHY OF THE LIVER IN A PREGNANT WOMAN: AUTOPSY.¹

BY SAMUEL CROWELL, M.D., DORCHESTER, MASS.

JAUNDICE and a sudden suppression of urine in a pregnant woman, lasting eight days and ending in death, is the story in a nutshell. We will go into the clinical history of this interesting case, however, more in detail.

Near midnight of November 15, 1893, I was consulted by a husband seeking aid for his wife, who was suffering from pain in the back and stomach. She was a primipara, at about the sixth month, age forty-two. She had always enjoyed the best of health, and had been entirely free from the many ills accompanying pregnancy. She attended a lecture in town that very evening, retired for the night in her usual health, but shortly afterwards began to complain of this pain, which no domestic remedy seemed to relieve.

November 16th. I was sent for in the early evening to see the patient. The quarter-grain of morphine of the night before had relieved the pain, and it had not recurred. The patient was bleeding from the gums, and had been spitting and wiping blood from her lips all the afternoon. The face, eyelids, lips, hands and feet were swollen. Headache, and vomiting of all nourishment taken into the stomach, had existed all day. On inquiry it was found that not a drop of urine had been passed for the twenty-four hours. The patient was about the house doing her work. At my request, she passed four ounces of bloody-looking urine, containing a large amount of albumen, granular and hyaline casts, renal epithelium and a few blood-corpuscles.

November 17th. I saw the patient in the morning by daylight. She was deeply jaundiced. This jaundice I believe to have been present from the first, but just when it appeared it was hard to say, as no one had noticed it, and the gaslight would have hidden its presence the night previous on my visit. She had vomited everything but cream-of-tartar water. The headache was less, she did not complain of it again until twenty-four hours before her death. The skin was moist from the attempts made to sweat her. The bowels had moved slightly from a dose of *ol. Tiglii*, and there was only two ounces of urine to show for the twenty-four hours' excretion of the kidneys.

November 18th. Condition the same; mind clear; no urine for twenty-four hours. Ten grains of calomel had produced one watery discharge.

November 19th. Condition the same; no urine.

November 20th. Condition the same; no urine.

The temperature taken at the time of my visits was generally normal, twice I found it 99°. The pulse ranged about 76 per minute.

November 21st. Condition the same; no urine. In the morning I started up labor with a bougie. The uterus responded, and in the evening I took away a macerated foetus at about the sixth month. The patient's condition was good. There was no flowing connected with the miscarriage and practically no discharge afterward.

November 22d. Condition the same; no urine. I

drew, with the catheter, five ounces from the bladder. In the afternoon a convulsion occurred lasting ten minutes, followed by delirium, requiring two to hold her in bed, and an intense headache and pain through the right eye. The tongue became thick and swollen, and the features expressionless. In the early evening she had a second convulsion of about the same duration. This was followed by delirium alternating with short lucid spells during the night, and ending in death at eight A. M., November 23d, on the eighth day of the disease.

At the autopsy made five hours after death, the heart and lungs were normal. No fluid in the serous cavities. Liver not descended below the ribs. It extended well over to the left side of the body, and seemed somewhat larger than normal. It was firm and smooth. The gall-bladder was not distended.

Specimens were sent to Dr. W. T. Councilman for examination. His report reads:

"There was brought for examination a portion of the liver, one kidney, spleen, a portion of the heart and of the uterus.

"The portion of the uterus brought had about the thickness and consistency of the uterus at the end of pregnancy. It was rather soft and of a pale-yellowish color. On its internal surface there were some adherent clots.

"The liver microscopically was of a dark green color. The bile-duct was not occluded at the autopsy. The kidney was very large, of a pale-yellowish color, with a distinct greenish tinge. The cortex was smooth. No appearance of hæmorrhage. On section, the cortex enlarged and pyramids congested. Markings obscure. On section, the cortex had the same greenish appearance as the surface. Cultures made from the organs gave pure cultures of streptococci in all of the organs. They were most abundant in cultures made from the uterus and spleen. The cultures from the liver and kidneys gave only a few colonies. The streptococcus found belongs to the general type of the streptococcus longus. It grew out in long thin chains, and the opposing surface was flattened.

"Microscopic examination of the tissues was made both in the fresh state and after hardening in various media. At the fresh examination a considerable amount of bile pigment was found in the kidney, with well-marked fatty degeneration, principally confined to the collecting tubules. Sections of the hardened organ showed a considerable degree of acute nephritis. The glomeruli were but little altered. The only change noticed was that the capillaries were somewhat thickened and indistinct. The epithelium of the convoluted tubules was swollen, fatty and in places distinctly necrotic. Accumulations of round cells and leucocytes were found in various parts of the parenchyma. Numerous casts were found in the collecting tubules. The liver showed, both fresh and hardened, an injection of the smaller bile-ducts with inspissated bile. There was marked fatty degeneration of the cells, and in places the cells were necrotic. No change was found in the heart other than a very slight fatty degeneration.

"The case appears to be one of general infection with streptococci proceeding from the uterus. The condition of the kidneys is probably to be referred to this. The jaundice and the lesions in the liver may have been due to other causes."

The autopsy is of great value to us in making the

¹ Read by invitation before the Obstetrical Society of Boston, December 9, 1893.

diagnosis, though it does not throw all the light we want; it fails to explain the jaundice. Without its assistance one would not be far out of the way in making a diagnosis of acute yellow atrophy of the liver, brought about by the general infection from the uterus, and especially aided in its development by the kidneys, except that percussion of liver dulness was too great.

Jaundice in pregnancy is of rare occurrence, and should always be looked upon as a grave complication, threatening the life of both mother and child, especially the life of the child, even where the jaundice is of benign origin.

Acute yellow atrophy of the liver is considered to be the cause of jaundice in a large proportion of the cases, though jaundice may be produced by the same causes as in the non-gravid state.

It is also stated that the pressure of the gravid uterus upon the liver is a cause of jaundice. This theory seems to me hardly tenable, when one considers the innumerable pregnancies where the liver must be greatly pressed upon without jaundice, and the few cases where it occurs are in those months of pregnancy before the uterus has attained sufficient size to cause pressure.

A CASE OF MYXEDEMA TREATED BY THYROID EXTRACT.¹

BY W. N. COWLES, M.D., AYER, MASS.

In view of the prevailing interest in the subject of myxedema and allied affections, I have prepared a report of the following case:

Mrs. S., aged forty-two years, is the oldest of a family of five children. Her mother, a brother, and three sisters are living and in good health. Her father died two years ago at the age of sixty-six years, after a long illness accompanied by gangrene of one foot. For many years previous to his death his eyes presented a bulging, staring expression, so marked as to attract the attention of all who saw him. He was of an excitable disposition, and his ability to work was limited by what his family called "nervousness and heart disease." His family physician says he had an excitable heart. There is no history of thyroid enlargement. A photograph of this man taken just before his last illness shows the characteristic facies of Graves's disease.

My patient, Mrs. S., has always been well until her present trouble began. Menstruation has always been regular except when interrupted by pregnancy. She is the mother of five children, three of whom are living. About seven years ago, soon after the birth of her youngest child, the patient noticed that she was getting bulky in body and awkward and weak in her movements. The trouble increased at a variable rate until July, 1893, when her condition was as follows:

The body bulky; the face, hands and feet distinctly swollen, the swollen surface not pitting on pressure. The skin was dry, harsh, thick, and always cold to the touch. There was a pale-yellow tint of the surface, suggestive of slight jaundice. Scaling of the epidermis was noticeable over the greater part of the body. The skin of the ends of the fingers was thick and cracked, and the nails seamed and brittle. The hair had a dry and broken appearance. The tongue was unusually broad and thick. Speech was slow and thick, as if the

tongue were too large for the mouth. There was apparent mental sluggishness, with an inclination to melancholy ideas. The temperature was always subnormal, 96° to 97° F. in the mouth. The thoracic and abdominal viscera appeared to be normal. The thyroid gland could not be felt. The patient complained of great weakness, of being easily tired, of shortness of breath on exertion, and of a constant feeling of coldness. She had noticed a lack of perspiration, even in hot weather. The urine collected for several days in succession in July, 1893, amounted to about two pints in twenty-four hours. Specific gravity, 1.024 to 1.026; color, pale; reaction, acid; sediment, normal; no albumen or sugar found.

On September 8th, Mrs. S. began taking desiccated sheep's thyroids, in doses of one-third of a gramme, three times a day.

Her condition at the time was practically the same as in July. Weight, 204 pounds; temperature, 96.4° F.

After three or four days of treatment the patient complained of severe pain in the lower extremities.

September 18th, the patient's weight was 192 pounds, the temperature 96.5° F. The amount of the remedy administered was reduced one-half, on account of severe pain in the lower extremities.

September 26th, weight, 190 pounds; temperature, 96.5° F.; no pain or discomfort of any kind. The remedy was increased to one gramme daily.

October 2d, weight, 186 pounds; temperature, 97.5° F. Severe pain in head and left shoulder. Dose of the extract again reduced to half a gramme daily.

October 7th, weight, 188 pounds; temperature, 98.2° F. The dose of desiccated thyroids was again increased to one gramme daily, and continued at that amount without further discomfort.

October 14th, weight, 182 pounds; temperature, 98.4° F.

November 12th, weight, 172 pounds; temperature, 98.6° F.

December 20th, no further change in weight. The patient's appearance has wonderfully changed. The swelling of the face, hands and feet has literally melted away. During the first six weeks of treatment there was marked anæmia, as shown by pallor of the mucous membrane. That condition is gradually giving place to a ruddy, healthy appearance. There has been a considerable desquamation of the skin, especially upon the hands and feet. The surface is warm to the touch. The yellow color has disappeared. The perspiration has returned. The condition of the nails and hair has improved, but is not yet normal.

A record of a number of urinary examinations made during the first two months of treatment shows an increase in amount to about four pints in twenty-four hours; specific gravity, 1.018 to 1.022, with no marked departure from a normal quality.

Quick movements, rapid speech, and an animated manner have taken the place of former slowness of speech and action, and stupid appearance.

This case appears to be especially interesting on account of the probable occurrence of exophthalmic goitre in the father of the myxedematous patient, Mrs. S.

A MEMBER of Sorosis says that every young girl should read Naphey's "Physical Life of Woman," a book called "Tokology," and Cook's "Mothers and Daughters."

HENRY JACKSON, M.D., SECRETARY.

REGULAR meeting, Wednesday, December 20, 1893,
DR. F. C. SHATTUCK in the chair.

DR. J. J. PUTNAM presented a paper on

THE FUNCTIONS AND THE THERAPEUTIC USES OF THE THYROID GLAND.¹

DR. W. N. COWLES reported

A CASE OF MYXŒDEMA TREATED BY THYROID EX- TRACT.²

DR. J. C. WHITE: I have not used this substance in the treatment of skin diseases, but judging by what I have read, it follows the rule of many new remedies in cutaneous therapeutics, that do not seem to produce in the hands of subsequent experimenters the results produced in the hands of those who published the first accounts. I should like to ask some of the gentlemen who speak of its action upon the growth of the hair in myxœdema, whether they noticed it produced such astonishing results in male patients. If it would make the hair grow in male patients, it would be quite different from making it grow in the female patient.

DR. PUTNAM: Most of the cases have been in women. I cannot answer from memory.

DR. F. C. SHATTUCK: Of my four cases two have been in males and two in females. In one male, a man of sixty-nine, the beard is distinctly thicker than it was before he took the thyroid extract. I think there is more change in the hair of the beard than in the hair of the head. My other male patient has been under treatment too short a time to give opportunity for observation in this respect. With regard to the loss of weight, which seems to be so common a feature in the treatment of myxœdematous patients, and which has led to the employment of the drug for obesity with good results apparently, it is interesting to note that in one of my cases there was a gain of twenty pounds in weight, coincident with great improvement; and the weight has been properly distributed. The waist and the neck have got smaller, and the legs of proper shape, which they were not before. That, as far as I know, is rather unusual. It has always seemed to me that this Brown-Séquard treatment by testiculin is by no means analogous to the use of thyroid. We call both the testicle and the thyroid, glands; but, physiologically, they have nothing in common. I was a good deal interested in a patient of mine at the hospital this winter, as vigorous, fine-looking a man as one could wish to see, who was castrated several years ago for some disease of the testicles without the slightest change of appearance, up to the present time at any rate.

DR. CLARK: In regard to a possible relation of the spleen to the thyroid gland, I think some recent experiments of Zanda are interesting. This observer performed thyroidectomy on dogs without any evil results in cases where the spleen had been removed at least a month before. He concluded from this that the thy-

roid probably neutralizes some toxic principle, apparently a product of tissue change sent into the blood by the spleen.

DR. PUTNAM: I did not speak of the therapeutics of myxœdema, because Dr. Shattuck recently read an interesting paper on that subject.³ I should like to add the fact that quite a large number of cases of cretinism have been published as much benefited by thyroid extract even where the disease had persisted to adult life. Two or three of these cases have been under the care of Dr. Osler, of Baltimore.

There is another interesting point that I meant to refer to, which has been made the subject of a good deal of experimental work, namely, the relation of animal food to thyroidectomy. It was first observed by Munk that some of his animals died after they swallowed lumps of meat; and that was thought to strengthen his theory that the result was due to injury of the nerves of the neck, but it was observed that if the extractive matters were removed from the lumps of meat by boiling that these results did not occur. On the other hand, it was found that if the animals were fed with strong beef broth that they apparently did die sooner, and experiments of this sort form a part of this recent series to which I referred, as having been just published in Virchow's Archiv.

DR. C. B. PORTER referred to the question of pregnancy. It was observed quite early that during pregnancy some of the symptoms of myxœdema seemed to grow less severe, and Dr. Murray suggested that the thyroid of the foetus might be doing duty for the lacking thyroid of the mother. Some doubt, however, is thrown on that by certain observations I have read. It was found by Coiztisni, that if rats were pregnant, they seemed to suffer more from thyroidectomy than if not pregnant.

It is also an interesting fact, to which Dr. Porter referred, that occasionally the cachexia does not seem to follow thyroidectomy, and that has been reported, I think, after complete atrophy of the thyroid in Graves's disease. It would seem that sometimes this may be due to the fact that accessory glands exist, but it does seem as if a person could get accustomed to do without the thyroid.

Reports indicate that not all observers find the same improvement in the use of these preparations of the thyroid in healthy persons. It would also seem that in persons in health the effects of the thyroid were temporary, that loss of weight only went on to a certain point, or was fluctuating.

A case reported by Dr. Bramwell and one or two of Vermehren's cases would seem to indicate that the improvement as regards the skin and nutrition at large, was not necessarily lasting.

THE Smithsonian Institute has received from the Peruvian Army Surgeon-General nineteen crania of pre-historic character. They are of interest because they show that in that far-off age the skull was trephined. In one instance the patient survived the removal of a fragment four inches long and one and one-quarter inches wide; the cavity was covered with silver. In one case the patient survived two trephinations, but died after the third. The instruments used were flint. — *Medical Standard*.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, December 9, 1893, the President, DR. CHARLES M. GREEN, in the chair.

DR. S. CROWELL, of Dorchester, reported, by intimation,

CASE OF ACUTE INFECTION SIMULATING ACUTE YELLOW ATROPHY OF THE LIVER IN A PREGNANT WOMAN: AUTOPSY.¹

DR. C. E. STEDMAN regarded the case as one of peculiar interest from the fact that the patient secreted only eleven ounces of urine in eight days, three of these being days of complete anuria. During the greater part of this time the patient appeared fairly well.

DR. C. G. CUMSTON said that the endometrium's well-known ability to absorb would account for this case of general infection.

DR. WM. INGALLS thought it was a very curious fact that the patient was in such good health previous to the attack. The case would suggest some antecedent cause.

DR. M. H. RICHARDSON thought the case was an extraordinary one and that its true origin was not yet found. The unusual points were the sudden onset, and the absence of marked constitutional disturbances. One would suppose that the pulse, at least, would be affected by the streptococcus infection.

DR. J. G. BLAKE would agree with Dr. Richardson that the case was certainly very obscure and not thoroughly understood.

DR. EDW. REYNOLDS said he believed a great advance was being made in our understanding of sepsis by the aid of bacteriology. Clinical experience had taught him that the sense of smell might be of little use in these cases, that severe sepsis might exist with absence of odor in the uterine discharges.

DR. M. H. RICHARDSON said that there was often no odor from pure cultures of certain septic bacteria, but that the degeneration of the tissues which followed with the addition of other bacteria resulted in the foul stench.

DR. C. M. GREEN saw the patient two days before death. From the appearances alone at this time one would wonder why it was necessary to keep the patient in bed. He had learned to believe, however, that in sepsis a sense of comfort and well being on the part of the patient was often of serious import. As to the odor this was not infrequently absent in cases of true sepsis.

DR. M. H. RICHARDSON reported

THREE CASES OF SALPINGITIS OF UNUSUAL EXTENT,² and showed the specimens.

DR. G. HAVEN mentioned reported cases where a preliminary operation was done in order to examine the contents of the tubes. He himself had operated some twelve or fourteen times with good recoveries in all except one who died of embolism on the ninth day. He thought that one could not operate too early.

DR. J. G. BLAKE would take issue with the treatment of the second case by laparotomy. Why not have drained through the vagina which would have been a perfectly safe operation. He has been treating cases in this way for thirty years. A case he had treated

in this way for a double abscess two years ago, gave birth to a child a few nights ago. He remembers another case where the abscess was very large and where the patient has had several babies since. Of course, the risk in opening the abdomen nowadays is very slight, but still there is some risk. Hence he would prefer to evacuate the abscess per vagina whenever that is possible.

DR. S. CROWELL referred to an abscess in the posterior cul-de-sac of the vagina which was opened through the vagina, but pointed later in the left iliac region.

DR. C. G. CUMSTON, late of Geneva, Switzerland, showed some instruments.

DR. G. HAVEN reported a case of rapidly growing fibroid of the uterus and showed the specimen. The patient, a woman of forty, had been examined within six weeks and nothing found. Since then the fibroid had rapidly developed and she had lost much blood during menstruation. The tumor was removed and the patient has made a perfectly good recovery.

DR. M. H. RICHARDSON showed a pregnant uterus removed for cancer of the cervix.

Recent Literature.

A Manual of Practical Hygiene. Designed for Sanitary and Health Officers, Practitioners and Students of Medicine. By W. M. L. COPLIN, M.D., and D. BEVAN, M.D. With an introduction by H. A. HARE, M.D. 140 illustrations. Philadelphia: P. Blakiston, Son & Co. 1893.

Great improvement has taken place in the past five years in the character of works pertaining to practical hygiene; and this book offers no exception to this statement. Its excellent treatment of the subject will make it a valuable hand-book for reference.

The general character of the book may be understood from the following list of subjects treated: Causes and Prevention of Disease, Individual Hygiene, Clothing, Food, Water, Air, Climate, Soil, Habitations, Sewage, Disposal of the Dead, Technic. The chapters on Climate and on Habitations are especially full and complete.

The following extract from the introduction sets forth the general scope of the book: "Heretofore the busy practitioner has often neglected hygiene, in its relation to private life, because the reliable books were, most of them, based on military needs. The architect has found that too often the stated scientific facts clashed with the utility of his building, and, as a result, in many instances serious hygienic sins were committed. It is to meet such cases that this book was planned and written; and that its objects have been accomplished will be evident to any one who is wise enough to study this important branch of knowledge in its pages."

Disease in Children. A Manual for Students and Practitioners. By JAMES CARMICHAEL, M.D., F.R.C.P. (Ed.), Physician Royal Hospital for Sick Children, University Lecturer on Disease in Children, Edinburgh. New York: D. Appleton & Co.

This handy little book takes up briefly the whole subject of pædiatrics, and finishes with an excellent appendix, containing directions for making the simpler dietary of children. It should meet with much favor.

SANITARY INSURANCE: A SCHEME.

UNDER this head, Dr. G. Walter Steeves writes in the January *Nineteenth Century* magazine, taking for his text the proposition that "thousands of deaths annually result from diseases which are in the most absolute sense preventable."

The complaint which he has to make is that under the existing social arrangements, there is no sufficient guaranty to the purchasers or lessees of tenements as to the perfect sanitary condition of such dwellings. It frequently happens that the first intimation of a sanitary defect in a house is an outbreak of a preventable disease, or one of those infectious maladies classed under the generic term "zymotic," such as diphtheria or typhoid fever. It is an acknowledged fact that people are living at the present day in habitations whose condition of healthiness is only tested by the sudden advent of an infectious disease, and it is equally true that a house is usually considered healthy till found unhealthy. If the wealthy may indeed carefully select their dwellings, the time has certainly not arrived in any civilized country when sanitary surroundings are a *sine qua non* with the masses; and the majority are only induced to inquire into such matters after serious illness has occurred, or some marked insanitary condition has been pointed out.

Despite the fact that the Health Department is a prominent feature with all our municipalities, that there are Local Boards and State Boards well equipped and that all our universities have departments for the study of hygiene and laboratories for bacteriological research, and that grand results have been accomplished by all these instrumentalities — it would appear from mortality statistics that the public are not yet sufficiently protected against insanitary dwellings and surroundings.

Dr. Steeves cites instances like the following, which seem to settle the question of the tenant's protection — such instances can be paralleled in the history of many municipalities:

Mr. A., a prosperous draper, with a family of young children, elects to lease a house in a presumably healthy suburban district; he himself is quite ignorant of sanitary matters, but is naturally anxious to be on the safe side; consequently, as soon as he has taken possession, he communicates with the Health Department, asking for an inspection. He is surprised to find that as he cannot complain of any nuisance, the services of the Board's officials are not at his disposal. He is next advised to call in a sanitary engineer, who may or may not be associated with some sanitary association, to make an examination of the premises. This time he is successful; he is satisfied with the report, pays his fee, brings his family from town, where they have always enjoyed good health, and settles down at his new fireside with a feeling of relief. Six months elapse, when suddenly one of his children complains of sore throat; the doctor is sent for, and to the horror of the parent, the patient is declared to be suffering from diphtheria. The doctor now notifies the local Board of Health; and the main drain of the house, on being carefully tested by the officials, is found faulty — cracked by the sinking of one of the walls of the house, or one of the joints underground has been badly cemented. A further examination reveals the fact that the earth in the immediate vicinity is sewage soaked.

If such an incident as the above were to be taken as a statement of sober fact, it would teach either that the engineer who made the first report was careless in his inspection, or that the drain had subsequently become defective; in any case the necessity of frequent sanitary inspections of premises is apparent. Dr. Steeves's especial contention is that the existing protective associations, while doing much good work, have not gone far enough. As for property that has been standing twenty or thirty years, inspections with the necessary testing, should be scrupulously conducted three or four times yearly.

The "scheme" which this writer proposes, is as follows (how far it is practicable we must leave to our readers to judge): It is proposed that any city or district may organize for itself a sanitary protective and insurance association founded for the purpose of providing the public with a source of protection against unsanitary dwellings and surroundings. The definite objects would be:

- (1) To examine into the sanitary condition of any building previous to tenancy, or after, and to afford skilled advice on hygienic matters or appliances, either on existing premises or on the plans of proposed arrangements of new buildings.
- (2) To issue certificates respecting the sanitary condition of dwelling houses and buildings.
- (3) To provide the means by which a cleanly and wholesome state of dwelling houses and premises may be maintained.
- (4) The sanitary registration of dwellings.
- (5) The insurance of buildings against a defective sanitary condition.

It will be seen from the above statement that such an association would have for one of its principal duties to keep yards clean, house-drains flushed, gullies cleared out, and all refuse promptly removed. Landlord and tenant would thus be relieved of needless worry.

It is a part of this scheme to insure dwellings against preventable diseases; it does not seem probable that this writer would advocate the indemnification of persons in the case of illness, for this would open the door to exorbitant claims. Nor is it quite clear on what principle damages could be assessed.

His notion is that dwellings are to be kept in sanitary repair by his hypothetical association in consideration of an annual premium paid by the owner, tenant, or both. In order that any property should be accepted by the association as a risk, it would be subjected to a stringent examination by both engineer and medical officer. Before this inspection could be made, a written permit must be obtained from the owner. The report with full details shall then be submitted to the members of council, who, with all the facts before them, assisted by the advice of their officials, would determine on an acceptance or rejection, as the case might warrant. When once the dwelling is insured, it will be the duty of the association to see that it is kept in a healthy condition. It is obvious that such a house would be subjected to frequent inspections, and minor defects would be at once corrected; it is also evident that all work (plumbing, etc.) would be performed by skilled and trusted workmen.

The review writer thinks that builders and landlords would favor this scheme, (1) because they would have an opportunity of having their property certified and registered; (2) they would be free from petty annoyances and frequent demand from tenants on account of unsanitary conditions arising from faulty traps, house-drains, etc.; (3) where the property was of such a high order as to warrant its acceptance by the association as an insurance risk, the owner would practically be rid of all responsibility.

The Boston Board of Health at the present time will, upon application, send one of its inspectors to examine the plumbing in a house or tenement where, on account of sickness or for other reason, there is cause to suspect an unsanitary condition — more than this cannot be undertaken without greatly increased resources. In other and smaller cities of this State a similar provision prevails, though the ability to respond to such demands is even less in proportion to the populations. The New York Board undertakes to do there about what the Boston Board does here.

Such an incident as the following, however, is not unheard of. In a large building, rented for industrial purposes, complaint is made by the occupants that the plumbing is defective. Inspection by the Board of Health shows that the complaints are well-founded, and that the defects are both grievous and dangerous to health. The owner is notified. Plumbers are employed, and several hundred dollars are expended.

Their work is approved by an inspector of plumbing in the department of the inspector of buildings. Upon re-examination, the Board of Health finds the condition of the plumbing as faulty as before, but the work having been accepted and approved by the inspector of the other department, the Board is powerless to take further action, the owner's money has been wasted, and the occupants are still exposed to the same danger and inconvenience.

It is not a new proposal to undertake the sanitary inspection of dwellings and of buildings as a private commercial enterprise, but we doubt if it hitherto has been successful from a financial standpoint. There is no doubt, however, that of two dwellings offered for lease or for sale, one of which carried a guarantee of its sanitary condition and the other not, the former should, and we believe would, command a better price than the latter.

SURGICAL TREATMENT OF CRIME.

IN the last issue of the JOURNAL, editorial reference was made to a curious bill lately presented to the Ohio Legislature for the treatment of condemned criminals by using them as material for physiological experiment, and then putting them to death under ether. This may be called the physiological treatment of crime.

We have, before this, on several occasions referred to a proposition which is not new, but which seems to commend itself to members of the medical profession in our Southern States, namely, that criminals should be reformed and held in check by castration, instead of by imprisonment and hanging. A correspondent, Dr. Bishop, of Smithsburg, Md., sends us his views on this subject, which are not without originality as set forth before the Medical Society of Washington County, under the title of "Surgical Treatment of Crime."

Dr. Bishop is impressed with the feeling that law is a curious business, and that lawyers are curious people, but he thinks there might be hope of improvement if the legal mind would give its attention to medical methods. This idea he develops as follows:

"If a case comes into court (the hospital for the care of social maladies being so called) for treatment for curative or preventive results, and a remedy should be proposed altogether rational and promising, its use is not permitted by the learned judge until a precedent for it has been discovered. Then the counsel in the case turn over the pages of legal lore to the times when people did not seem to know much of their own affairs, and if they find something like the case in hand (like it, because it is not like anything else), then they employ it as a remedy, — not otherwise. Under such circumstances it is hardly matter for wonder that the disease keeps ahead of the remedy, or that the law's delay should be a proverb and a threat against honest business. It is not so in medicine. If a physical malady occurs, all scientific methods are at once invoked to discover its nature and an efficient remedy and preventive. Chemistry, microscopy, physiology, are all employed. The profession everywhere is enlisted in the investigation.

One doctor is never employed by anybody to defeat the honest efforts of another.¹ Under such conditions it is hardly marvellous that there should occur marvellously contrasting results. In court, in equity cases so-called, the chances are largely with the rogue."

Returning to the subject of surgical treatment of crime, he says:

"Crime of all kinds is on the increase; our jails and almshouses and other asylums are filled with its products. Lynch-law cases (the signal-lights of lost confidence in courts of justice) are flashing everywhere every day, and everyday business transactions are largely based on individual integrity.

"On the other hand, it need only be mentioned that the average of human life is being gradually raised. Not only that, however, but all the deadly diseases of the past are under virtual control.

"Population is no longer decimated. People no longer fly in insane fear from house and home at the approach of cholera or yellow fever where medical men hold sway.

"Seeing that these things are so, would it not be wise for the one profession to borrow the methods of the other? Nay, would it not be even better to profit by both their example and assistance?

"The medical profession have long since shown that criminals are of germ origin, some peculiar character or condition of the spermatozoon resulting inevitably in the production of a criminal. The saying, '*Nascitur non fit*,' is as true, therefore, for the criminal as it is for the poet. Now, the doctors have found that the true way to prevent diseases of germ origin is to prevent the germ; and if the law wants to prevent criminals, the sure way to do it is to sterilize the parent criminal, and the only way to do that is to castrate him. Of course there will be a thousand objections urged against the remedy, only two of which will be worth answering. One will be cruelty, the other danger to life, both of which are already negated by anaesthesia and asepsis. Doubtless there will also be the epithets 'uncivilized' and 'unchristian' applied to such treatment. But how will prevailing methods of treating criminals compare with this? Now they are penned up together to fester and ferment into more and more repulsive and dangerous criminal forms,—the petty thief emerging in form of a daring robber and the robber in the shape of a murderer.

"The practical effect of it all is the production of murderers by cultivation and breeding and the subsequent slaughtering of them by hanging. The thief, especially a bank thief, is imprisoned until the baby is weaned; but the spots of the leopard change not and the thief remains a reproducing thief in spite of legal punishment. How simple and how clean and how effectual the germicide method! You destroy the germ factory of the thief and so reform the thief himself more surely and effectually than all the prayers of the righteous would do it and prevent the production of thieves. If you do not breed thieves you will not have them.

"We owe it to the old English custom of hanging thieves that we are now as well rid of them—more than we owe it to moral suasion.

"One curious result of the treatment would be the settling of the race problem.

"Castration would hardly be a hardship to the negro. It has been practised upon members of the race from all time.² The harem of the Turk is always supplied with

negro eunuchs. Why they were selected we may never know. Possibly it was because there were individuals who could be restrained in no other way. Of course a law declaring all crimes not punishable by death shall be punished by castration would not be tolerated by the Constitution as it is now written. But a law could be enacted punishing all slighter crimes by an exceedingly severe flogging, but releasing the criminal upon producing proof of recent castration. There is a Japanese law which secures the destruction of State offenders by restoring to the family the estate if they could prove that the offender had committed suicide. Truly wonderful is aseptic surgery: it enables us to literally obey the Scripture which enjoins us to cut off the offending member. It is, of course, taken as understood, that lady criminals are meant also, it being as easy to cure one as the other."

DISSECTION IN THE PUBLIC SCHOOLS.

It seems to be dawning upon the minds of some of the members of the Boston School Committee that a foolish thing was done when the Committee passed a vote recently, prohibiting all dissection of animals in the public schools. The idea apparently was that, if zoology could not be taught without dissection, so much the worse for zoology. Some members of the Committee, however, have now sufficiently recovered their mental equilibrium to admit that a cold-blooded animal, a fish or an oyster, for instance, may be dissected, but a warm-blooded animal may not.

This somehow suggests the art-code of members of our common council, that little boys in diapers or panties may be done in stone, but little boys without may not.

At the last meeting, on Wednesday evening, it was voted, after a sharp discussion, that dissection of animals be allowed in the public schools, and so the question returns to the *status quo ante*. We are not by any means enthusiastic that zoology should be taught in the public schools—certainly not in the grammar grade; but if it is to be taught at all, there is but one way to teach it—thoroughly, by means of dissection.

MEDICAL NOTES.

A SPECIAL VACCINATION TRAIN.—The Pennsylvania Railroad Company has sent out a special train with two physicians, who are to go over the whole line to Chicago and vaccinate at each station all the switchmen, section-men, gate-keepers and other employes.

THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.—The Medical Society of the District of Columbia will celebrate the seventy-fifth anniversary of its organization in Washington, on Friday, February 16th.

A NEW MEDICAL QUARTERLY.—Dr. Joseph M. Matthews, of Louisville, Ky., has issued the first number of his new quarterly journal devoted to the diseases of the rectum, gastro-intestinal diseases, and rectal and gastro-intestinal surgery.

¹ Except in giving expert testimony.

² Until they have become quite used to it.

A NEW ITALIAN JOURNAL.—Guido Baccelli, M.D., Minister of Public Instruction in the Italian Cabinet and Director of the Medical Clinic in Rome, is to edit, with the association of Dr. Durante, a new Italian medical journal, *Il Policlinico*, a periodical of medicine, surgery and hygiene.

THE ACADEMY OF MEDICINE BUREAU OF NURSES.—The New York Academy of Medicine has established a bureau of nurses which was opened February 5th. Each nurse is charged a registration fee of two dollars; and a complete record of all her cases is kept on file, with the report of the attending physician as to her work. It is hoped to have the bureau open both by day and night as soon as it is sufficiently organized.

THE SECRETARY OF THE WISCONSIN STATE BOARD OF HEALTH.—U. O. B. Wingate, M.D., M.M.S.S., of Milwaukee, has been elected Secretary of the Wisconsin State Board of Health, to succeed J. T. Reeve, M.D., who retires June 1st next, after serving in that capacity since the board was organized, nineteen years ago. Dr. Wingate's term of four years as Commissioner of Health of Milwaukee, expires in April next; about two years ago he was appointed on the State Board of Health for a term of seven years by Governor Peck.

THE PROTECTIVE INFLUENCE OF VACCINATION.—The report of the medical superintendent of the hospital-ships of England is strongly corroborative of previously recorded experience as to the protective influence of vaccination in safeguarding nurses and members of the staff of small-pox hospitals against an attack, and more especially a fatal attack, of that disease. Of 1,201 persons employed on the staff of the hospital-ships during the years 1884 to 1892, only six, or one-half per cent., contracted small-pox, and all of those attacked recovered.

THE INTERNATIONAL MEDICAL CONGRESS.—The Minister of the Treasury of Italy has awarded the sum of 80,000 lire (\$6,000) from the reserve fund of the treasury, toward the expenses of the Eleventh International Medical Congress of Rome. This is given as a temporary instalment pending the meeting of parliament, when a special bill for an adequate contribution from the State will be presented by the ministry.

THE INTERNATIONAL SANITARY CONFERENCE AT PARIS.—The International Sanitary Conference which was to have met in Paris during the last week in January for the consideration of measures to control the cholera in the Red Sea and Persian Gulf in connection with the Pilgrimages to Mecca, was postponed by the French Government owing to incomplete arrangements made by other countries, especially Turkey which appointed no delegates. The postponed meeting was opened on the 7th of February, and the members were received by President Carnot, who welcomed them to the warmest hospitality in the name of the Republic.

PRELIMINARY PROGRAMME OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.—At the Congress of American Physicians and Surgeons to be held in Washington May 29th, 30th, 31st, and June 1st, the following subjects have been selected for discussion: By the Association of American Anatomists, "Morphology as a Factor in the Study of Disease"; by the American Climatological Association, "Sewer Gas"; by the American Dermatological Association, "The Distribution and Control of Leprosy in the United States"; by the American Association of Genito-Urinary Surgeons, "Nephritis in its Surgical Aspects"; by the American Gynecological Society, "The Conservative Surgery of the Female Pelvic Organs"; by the American Laryngological Association, "The Surgery of the Accessory Sinuses of the Nose"; by the American Neurological Association, "The Influence of Infectious Processes on the Nervous System."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—During the week ending at noon, February 14th, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious diseases: diphtheria 24, scarlet fever 44, measles 10.

REPORT ON STATE CONTROL OF VACCINE FARMS.—At the next meeting of the Section for Clinical Medicine of the Suffolk District Society, Wednesday, February 21st, Dr. D. D. Gilbert, of Dorchester, will give the report of a Committee appointed by the Norfolk District Society to investigate the various vaccine farms with reference to State control. The Committee was appointed to act with the aid of the Suffolk District.

THE MASSACHUSETTS GENERAL HOSPITAL.—At the meeting of the Corporation of the Massachusetts General Hospital last week, the following officers were elected: President, Charles H. Dalton; Vice-President, John Lowell; Treasurer, Franklin Haven; Secretary, Thomas B. Hall; Trustees on the part of the Corporation, Arthur Astor Cary, Edmund Dwight, Samuel Eliot, William Endicott, Jr., Thornton K. Lothrop, Nathaniel Thayer, Henry P. Walcott, Roger Wolcott. The Governor has sent to the Executive Council the following nominations as trustees of the hospital on behalf of the State: Charles T. Bemis, of Medford; David P. Kimball, Thomas E. Proctor, and William S. Bigelow, M.D., of Boston.

COST OF THE SMALL-POX EPIDEMIC IN LOWELL.—There were eight cases of small-pox in Lowell during the recent epidemic. Their occurrence cost the city nearly \$7,000. This sum includes the hospital expenses and the cost of the free public vaccination.

NEW YORK.

CHILDREN IN FACTORIES.—The State Factory Inspectors, in their annual report, transmitted to the legislature on January 31st, state that the number of children under sixteen found employed during 1893, was a fraction under 84 in each 1,000 persons, as against

38 during 1892, and 112 in 1887; showing a decrease of about 10 per cent. over 1892 and of 70 per cent. over 1886, when the law restricting the employment of children went into effect.

A RECEPTION TO THE SURGEON-GENERAL.—On Tuesday evening, February 6th, Mr. William Wood, the publisher, gave a large reception at his residence on 63d Street in honor of the new Surgeon-General of the United States Army, Dr. George M. Sternberg, at which there were present a representative gathering of the medical profession of New York and a number of other guests.

A FIRE AT THE MEMORIAL HOSPITAL IN BROOKLYN.—On the evening of February 5th there was a serious fire at the Memorial Hospital for Women and Children in Brooklyn, which broke out in the operating room. All the patients, however, were successfully removed to the nurses' dormitory. The hospital is a three-story frame building, and it will be some time before the damage inflicted can be repaired. A longer and more substantial building is now in process of construction, and funds are being raised for its completion.

TRANSFUSION OF BLOOD IN ASPHYXIA FROM ILLUMINATING GAS.—In the case of a woman asphyxiated with illuminating gas recently admitted to the Long Island College Hospital, Brooklyn, all other remedies having failed to relieve the patient, transfusion was resorted to, and the blood for the purpose was generously supplied by the house-surgeon, Dr. Franklin W. Kemp. There was some temporary improvement after the operation, but she died the following day. A young girl, seventeen years of age, who had slept in the same room with this patient and had also been overcome by the gas, was successfully treated by the ordinary means.

SMALL-POX.—During the week ending February 10th, 28 cases of small-pox were reported, with 9 deaths, against 22 cases and 4 deaths the previous week; and 594 cases of measles, with 19 deaths, against 554 and 20 deaths the previous week. The other contagious diseases showed a decrease. There were reported 129 cases of scarlet fever, with 16 deaths, against 151 cases and 20 deaths the previous week; diphtheria, 190 cases and 59 deaths, against 197 cases and 58 deaths. The total number of deaths in the city was 868, an increase of 20 on the week ending February 3d.

PHILADELPHIA.

PROTECTION OF WATER-SUPPLIES IN PENNSYLVANIA.—A conference of county and other local boards of health of the State of Pennsylvania was held at Harrisburg during the week ending January 29th. The preservation of the water-supplies of communities from pollution was discussed, and a resolution adopted pledging all boards of health in the commonwealth to do all in their power to prevent contamination of the inland waters of the State. In a paper read by the Health Officer of Philadelphia the work done by the

Woman's Health Protective Association in stimulating sanitary reforms, such as keeping streets clean, removing nuisances, and improved household hygiene was referred to in the highest terms of approbation. The communications read were generally of a very practical and useful character. It was decided to form a permanent organization, which is to hold annual meetings at Harrisburg. The name adopted is "The State Association of Health Authorities of Pennsylvania." All persons officially connected with boards of health of this commonwealth shall be members, and honorary members may be elected from those who have rendered distinguished services to sanitation. Committees on Legislation and on Publication were provided for, besides an Executive Committee. The following officers were elected for the ensuing year: President, Hon. Robert E. Pattison (the Governor of Pennsylvania). Vice-President, Major Moses Veale, Philadelphia; Hon. Thomas P. Merritt, Reading; J. H. McClelland, M.D., Pittsburgh. Secretary, Wm. B. Atkinson, M.D., Philadelphia. Treasurer, Jesse C. Green, M.D., West Chester. At the first session, Dr. Walter Wyman, Supervising Surgeon-General United States Marine-Hospital Service, and Dr. J. H. Rauch, of the Illinois State Board of Health, were elected honorary members of the Association. This recent development in public health work is principally due to the zeal of Dr. Benjamin Lee, the secretary of the State Board of Health.

Miscellaneous.

THE STUDY OF PEDIATRICS.

DR. W. S. CHRISTOPHER¹ makes an earnest plea for the more general and thorough study of the diseases of children. As it is the most immature department of clinical medicine, so it offers one of the richest fields of work for the student and pioneer. "Internal medicine," he says, "is taught almost universally from the standpoint of the adult, and pediatric manifestations of disease are only incidentally referred to. The consequence is that the new graduate is afraid of a baby, readily accepts the diagnosis of the grandmother, and not infrequently follows her treatment."

Another important factor in the retardation of the study of infantile disorders is the inherent difficulty of diagnosis. While the infant has not the power of speech, yet it does possess a very distinct and quite full language, the acquirement of which, however, demands faithful and persistent effort on the part of the practitioner. This language is quite as difficult to acquire as the manual skill needed in so many of the mechanical departments of the profession.

The foundation of the new work lies in the study and appreciation of the normal processes of growth, and of the development of functions which at birth and in infancy are so immature as practically to be non-existent. The anatomy and physiology of infancy and childhood are as much a part of pediatrics as is their pathology.

The great importance of environmental factors in

¹ American Journal of Obstetrics, January, 1894.

the child's development is to be borne in mind: both the nutritive, the sanitary and the psychic. All are to be considered. Infant-feeding is not the whole of pediatrics, though, from the clinician's standpoint, it is the most important single factor.

The advantage gained from this systematic study of disease in children is not the child's alone. Much light will be thrown upon disease as it occurs in adults, and a keener appreciation of many conditions will be possible. The study is important for the great light which it will shed upon the diseases of adults, for the better alleviation of the sufferings of the helpless little ones, and for the broader and nobler, because farther-reaching, purpose of improving the race.

SIR ANDREW CLARK ON OCCUPATION.

In the course of a most interesting lecture on the treatment of fibroid phthisis,¹ Sir Andrew Clark makes the following observations on occupation, which show clearly the peculiar quality which gave him his wonderful control over his patients. After speaking of the prime importance of proper food, clothing and exercise, he says:

"Another point about the management of those cases is occupation. If people are wonderfully well off in life, and a member of the family falls sick or becomes delicate, they are disposed to take him away from work on the ground that work is bad for him. I do not agree with them at all. I think that is about the biggest mistake that you will have to encounter. *Labor vita vita est.* Labor is the life of life; and especially is it the life of life to the delicate. And when any organ is sick it is then truer than in health that even in sickness and delicacy it is better for the organ to do what work of its own it can, provided it can do it without injury. And I can say to you from a considerable experience of tuberculous pulmonary disease, I can say with perfect confidence, that those who have done the best have usually been those who have occupied themselves the most. . . . Then comes tranquility of mind. Yes, labor is life, but worry is killing. It is bad management that kills people. I am frequently told that such and such a man has overworked himself. Nature will let no man overwork himself unless he plays her false—takes stimulants at irregular times, smokes too much or takes opium. If he is regular and obeys the laws of health and walks in the way of physiological righteousness, nature will never allow him or any person to work too much. I have never yet seen a case of breaking down from mere overwork alone; but I admit that it is necessary above all things to cultivate tranquility of mind. Try to help your patients to exercise their wills in regard to this, for wills count for something in securing tranquility—to accept things as they are, and not to bother about yesterday, which is gone forever; not to bother about to-morrow, which is not theirs; but to take the present day and make the best of it. Those affectionate women who will continually peer into what lies beyond never have any present life at all—they are always grizzling over the past or prying into the future; and this blessed to-day, which is all that we are sure of, they never have."

¹ Lancet, January 6, 1894.

Correspondence.

THE VERMIFORM APPENDIX.

CLINTON, IOWA, February 10, 1894.

MR. EDITOR:—Recent articles on appendicitis have suggested to my mind that if the vermiform appendix is of no use to its possessor from his birth to his death, it follows that its period of usefulness must have preceded his birth. In that case it must be a remnant of the umbilical cord, and should have been removed at birth, as is the custom, beyond a doubt, among the brute creation. The depression of the human navel, as compared with the smooth cicatrix of the brute, indicates a different condition of the interior of the abdomen of the one as compared with that of the other.

My belief that animals remove this from the body of their young at birth, rests on the fact that I have witnessed the operation. Over a dozen years ago I befriended a little female dog in her hour of travail, and, instead of concealing, she seemed to take pains to make evident to me what services she rendered her young. Cautiously, with the points of her teeth, she made an incision around the umbilical cord about an inch from the body. This incision disclosed an inner membrane sheathed within the outer one. Grasping this inner membrane with her teeth and pushing with her forepaws on the little body, she pulled vigorously at the membrane, withdrawing quite a quantity through the umbilical orifice and out of the body of the pup. When she had removed all that would yield to her efforts, she bit it off and carefully and neatly chewed together the severed edges of the part that remained. Then commencing at the hind quarters of the little thing, which was lying limp and helpless, she gave it a vigorous licking with her tongue. Every sweep of her tongue seemed to give it life, and also to raise it slightly, when it would fall back again. She persevered and soon had it nearly upright, standing on its head and shoulders; but she did not leave it till she had thoroughly licked it all over and had brushed every hair into its proper place.

I have reason to believe that this custom prevails among all animals, though they perform the operation in a manner to defy the curiosity of man. The instinct of the brute prompts her to devour ravenously, everything ejected with her young. Having consumed all that is visible, she pursues the invisible, which she extracts by suction, while ostensibly she is merely licking her offspring. The ripples that pass through the little one, and the contortions it involuntarily undergoes, testify, however, to some change which is occurring within, such as, possibly, the removal of a separate tissue enveloping each individual organ.

If, as the Scripture teaches, our first parents were created, not born, and created in the image of One who was not born, there could be no *raison d'être* for a navel. On the other hand, if mankind is an evolution from the animal, why did his reason bid him discard a practice which he had followed with success as a brute? We seem to hold a chain which stretches back, link by link, through past generations, till we reach a point coeval with the Fall of Man. Is it a cause or a result?

Looking forward, however, what might be the result if man would learn of Nature from the brutes around him? To the infant, immunity from pain, a life as healthy as any little animal; to the woman, a vast decrease in the pains of gestation and parturition; to mankind at large, less liability to hereditary disease and a freedom hitherto unknown from those unnatural appetites which sink man below the level of the brute, and lead to insanity and suicide.

Certainly, the subject is well worthy of investigation; and the solution of the problem would tend to raise man to a plane far above his present level; and the generations of the future, by avoiding the mistakes of their forefathers, would attain the perfect type of the human form divine.

Very truly yours,

MARGARET C. HAYES.

METEOROLOGICAL RECORD.

For the week ending February 3, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,811: under five years of age 1,090; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 377, acute lung diseases 467, consumption 300, diphtheria and croup 190, scarlet fever 47, measles 39, typhoid fever 28, diarrhoeal diseases 26, cerebro-spinal meningitis 18, whooping-cough 18, erysipelas 10, small-pox 6.

From typhoid fever Philadelphia 6, New York, Cincinnati and Lowell 4 each, Brooklyn 3, Cleveland and Pittsburgh 2 each, Boston, Milwaukee and Springfield 1 each. From diarrhoeal diseases New York, 13, Cincinnati 4, Brooklyn and Milwaukee 3 each, Charleston, Fall River and Somerville 1 each. From cerebro-spinal meningitis New York 8, Cleveland 2, Brooklyn, Washington, Worcester, Lynn, Holyoke, Chelsea and Amesbury 1 each. From whooping-cough Boston 4, New York and Washington 3 each, Philadelphia and Milwaukee 2 each, Cincinnati,

Cleveland and Fall River 1 each. From erysipelas New York 5, Philadelphia 2, Boston, Pittsburgh and Lowell 1 each. From small-pox New York 4, Brooklyn and Boston 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending January 27th, the death-rate was 20.7. Deaths reported 4,156; acute diseases of the respiratory organs (London) 422, whooping-cough 192, diphtheria 80, measles 73, fever 42, diarrhoea 42, scarlet fever 35, small-pox (Birmingham 7, Bradford 3, Bristol 2, London, Nottingham, Liverpool and Halifax 1 each) 16.

The death-rates ranged from 14.8 in Derby to 31.1 in Norwich; Birmingham 25.8, Bradford 19.6, Croydon 17.7, Halifax 18.5, Hull 18.6, Leeds 18.8, Leicester 14.9, Liverpool 24.6, London 19.8, Manchester 23.8, Newcastle-on-Tyne 19.9, Nottingham 18.9, Portsmouth 16.8, Salford 30.1, Sheffield 19.7, Sunderland 16.5, West Ham 16.0.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 3, 1894, TO FEBRUARY 9, 1894.

The following named officers of the medical department are relieved from duty in this city, to take effect upon the completion of the present course of instruction at the Army Medical School, and are assigned to duty at the stations hereinafter designated: FIRST-LIEUT. WILLIAM W. QUINTON, assistant surgeon, Fort Riley, Kansas; FIRST-LIEUT. THOMAS S. BRATTON, assistant surgeon, Fort Niobrara, Nebraska; FIRST-LIEUT. DRANE C. HOWARD, assistant surgeon, Fort Buford, North Dakota; FIRST-LIEUT. ALEXANDER S. PORTER, assistant surgeon, Fort Keogh, Montana; FIRST-LIEUT. WILLIAM H. WILSON, assistant surgeon, Fort Leavenworth, Kansas.

Leave of absence for two months, with permission to go beyond sea, is granted MAJOR ROBERT M. O'REILLY, surgeon, U. S. A.

FIRST-LIEUT. BENJAMIN BROOKE, assistant surgeon, is relieved from duty at Fort Leavenworth, Kansas, to take effect upon the arrival of FIRST-LIEUT. WM. H. WILSON, assistant surgeon, at that post and ordered to Camp Pitot, Butte, Wyoming, for duty.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 10, 1894.

FRANK C. COOK, assistant surgeon, ordered to the Naval Laboratory and Department of Instruction, New York.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, February 21st, at 8 o'clock.

Papers: Dr. D. D. Gilbert, of Dorchester, will give the report of a committee appointed by the Norfolk District Medical Society, to investigate the production of "Vaccine Virus."

Dr. A. P. Chadbourne will read on "Fibroid Phthisis."

F. C. SHATTUCK, M.D., Chairman.
HENRY JACKSON, M.D., Secretary.

RECENT DEATH.

THEODOR BILLROTH, M.D., professor of surgery in the University of Vienna, died at Abbazia, in Austria, February 6th, aged sixty-four years. He was born on the Island of Rugen, in the Baltic, and received his education in arts and medicine at Göttingen, Berlin and Vienna. In 1855 he was assistant to Langenbeck at the clinic. In 1859 he was made professor at Zurich, but returned to Vienna in 1867 where he has since remained. During the Franco-Prussian War he had charge of the military hospitals on the Rhine. In 1881 he performed successfully the first operation of pylorotomy for cancer of the stomach. Of his numerous writings his work on "Surgical Pathology" is probably the best known.

FOUR CASES OF MYXŒDEMA TREATED BY THYROID EXTRACT.

BY FREDERICK C. SHATTUCK, M.D.

THE evolution of our knowledge of the functions of the thyroid gland and the interdependence of atrophy of the gland and the disease which, following Ord, we call myxœdema, will constitute, I think, one of the most interesting chapters of the medical history of our time. Cretinism, endemic and sporadic, had long been known when the late Sir William Gull, just twenty years ago, published his paper on "A Cretinoid State Supervening in Adult Life in Women." The next important step was taken when the Swiss surgeons, Kocher and Reverdin, recognized the identity in symptoms of the cases described by Gull and certain cases in which total extirpation of the thyroid gland for goitre had been practised. Then came the confirmatory experimental evidence derived from extirpation in animals, notably dogs and monkeys, and complete demonstration that the thyroid gland plays an extremely important rôle in the economy, profoundly influencing the nutrition of the central nervous system, and through it of the skin and its appendages in particular. Antiseptic surgery rendered the next step possible — the transplantation of the thyroid gland. Temporary improvement followed this procedure: but it was only temporary, as a rule, inasmuch as the gland underwent absorption instead of rooting itself and persisting as such. The disease thus remained of great clinical and pathological interest, but was considered practically not amenable to treatment. For instance, Osler's "Practice of Medicine," the prefatory note of which bears the date January 1, 1892, says: "Unfortunately, no satisfactory treatment is known. The patients suffer in cold and improve gradually in warm weather; they should therefore be kept at an even temperature and should, if possible, move to a warm climate in the winter months." How differently would this passage have been worded January 1, 1893!

To Dr. George Murray, of Newcastle, England, belongs the credit of the practical introduction of our present brilliantly successful treatment. In 1891, he began the hypodermic injection of a glycerine extract of the sheep's thyroid. The obvious dangers and inconveniences of this method led to the attempt to attain the same good results by the feeding of the raw gland, finely minced, to myxœdematous patients. *Mirabile dictu*, gastric and intestinal digestion were found not to impair the efficacy of the gland, and it was proved to be still active even when moderately cooked. Under these circumstances it is not to be wondered at that dried or liquid extracts of the gland, which offer convenient modes of administration, are found to be thoroughly effective. We are still much in the dark as to exactly what the gland does in the economy and how it does it, and we must probably look to physiological chemistry for the answer to these questions. The interest of the subject is so great that I have not been able to refrain from these introductory remarks to a brief report of four cases in private practice which I have thus far treated by thyroid extracts.

CASE I. This is, as far as I know, the first thus treated in this country, and presents some points of

special interest. Miss A, twenty-nine years old, first consulted me April 21, 1892. Her maternal great-grandmother and great-aunt and her paternal grandmother died of cancer; otherwise the family history is unimportant. The catamenia appeared during the thirteenth year, and were regular. She was well until she reached the age of seventeen, when she left school on account of frontal headache and nervousness. For the next five or six years she was anæmic and lacked strength. The catamenia diminished in amount and she had leucorrhœa; but she did much as other girls, nevertheless, and was fond of dancing, in which she excelled. In 1885, much arsenic was found in the cretonne and wall-paper of her room. These articles were removed, and she improved somewhat; but remained physically below par. In October, 1890, she took carbonate-of-iron pills, and by January 1, 1891, considered herself perfectly well. In January, 1891, normal menstruation appeared; February was skipped; in March, May and June there was a slight flow; but the period has been entirely absent ever since, nor has there been any return of the leucorrhœa. In February, 1891, she began to gain weight, and since then had put on twenty pounds, especially about the face and bust. The complexion, which was formerly fair and delicate, had become coarse and red, and her appearance had so changed that she was often not recognized. Within a few months the palms of the hands in particular, but also the soles of the feet and portions of the integument covering the neck and trunk, had acquired a peculiar yellow color. This could also be detected on the mucous membrane of the inner surface of the lips. The skin was generally rather coarse and rough, but was deeply fissured and cracked toward the finger-tips. The coloration of the fingers, combined with the roughness, led Dr. Osler, who saw her with me, to compare the skin to the covering of a goose's foot. The nails were brittle and uneven, the hair thin and dry. The patient herself questioned whether the color of the fingers could be attributed to oranges, of which she had eaten many of late; but she observed that she could not wash or scrub the color off, and that it did not disappear when she temporarily omitted this fruit. She stated that three years ago, and several times since, she had awaked in the morning to find blisters (herpes?) on her nose. Lately she had had two small red bunches on her eyelids. One was removed by Dr. Cheney; the other disappeared spontaneously. Later she had another which I saw, and which looked like a sty, though it did not suppurate. Within two years a vaginal examination had been made by a competent hand, which discovered nothing amiss. In past years she had consulted specialists for her hair, and a throat specialist, and had been under the care of several physicians one after another.

Visceral examination was negative and the temperature normal. There was no mental or physical sluggishness; indeed, subsequent evidence would suggest that she was at this time mentally elated rather than depressed or indifferent. She was not strong; but complained chiefly of her changed appearance, coarse complexion and unevenly distributed gain in flesh. Perspiration was slight or absent. Her appetite was very large, digestion good, but sleep very poor, not more than four hours a night. I examined the blood, though I made no regular count, nor did I estimate the hæmoglobin. I considered it practically normal

¹ Read before the Boston Society for Medical Improvement, December 11, 1893.

as did Dr. Osler some weeks later. The urine was normal in amount and not very significant. It contained constantly a very faint trace of albumen, uric-acid crystals, once a few hyaline casts, and a trace of arsenic ("A small trace in comparison with most cases of arsenical poisoning," Dr. Wood reported to me). Supraclavicular pads were present.

Suspecting myxœdema, though the case differed decidedly from those I had seen or read of previously, I sent her to Dr. J. J. Putnam, providing that he should not know my opinion before he stated his own. He was inclined to call it obesity with menstrual disturbance, rather than myxœdema. A few weeks later Dr. Osler saw her, and concurred in my diagnosis. I then began injections of a glycerine extract of sheep's thyroid prepared for me with every precaution by Dr. A. C. Jelly, who visited the abattoir weekly himself, and kindly took infinite pains, thanks to which no undesirable local symptom was ever produced. The extract obtained from one gland was injected every week in three doses for about three months by myself and Dr. Charles Folsom, who kindly assumed charge of her during my vacation.

For the last year she has not been under my care, as she lives out of town and has been unable to come in. During this year she has taken the dried extract of Parke, Davis & Co., and is now taking the New York glycerine extract by the mouth. At first, there was improvement in the condition of the skin, but I now believe that was attributable to the warm weather rather than to the treatment, which has been of no real benefit to her. About the middle of May an ecchymosis appeared on the right thigh as large as a small lemon. She had received no blow or injury so far as she knew, and the injections were all made in the back. In August, 1892, she began to be depressed mentally, and several times tried to end her life; indeed, for the last year she has been watched incessantly. The chief effects attributable to the thyroid administration seem to be loss of flesh, strength and appetite. A number of months ago a swelling near the left angle of the jaw appeared and discharged pus.

Dr. Cutler, of Waltham, under whose care she now is, kindly writes me that the left cheek is riddled with sinuses, and new abscesses occasionally form. He also says: "There is no violence, and apparently no hallucination or delusion, unless it may be a delusion when she says she cannot possibly move while almost in the act of walking. She is much depressed, and indeed quite desperate often, for she is certain she shall never be better. She has an intense præcordial distress often, which I judge to be the præcordial pain of melancholia. The hair is still falling, but new is growing. The skin and nails are still dry and rough. Speech is slow, but perfectly rational. She probably still retains her suicidal inclination, but does not manifest it in any way except in an occasional doubtful word."

Her mother writes under date of December 8, 1893: "There are black and blue marks on her legs, which, indeed, are so thin that they look like two sticks. Her face is swollen, also her waist, but the chest is hollow. The eyelids are swollen; the eyeballs often protrude. Her weight, which was 135 pounds when she first consulted you, is now less than 99. The under eye-lashes have gone. In July, 1892, her bust measured 40 inches; in October, 1893, 36 inches. In

July, 1892, her waist measured 33 inches; in October, 1893, 29 inches."

I permit myself a few remarks on this case here, as it is sharply contrasted with the others which I am about to report. I confess that the failure of the appropriate treatment is a point against the correctness of the diagnosis of myxœdema in this case. If it be not myxœdema, I am at a loss what to call it. Dr. Mitchell Clark² reports two cases of failure, the only two I have been able to find in which treatment has been ineffectual. The treatment lasted two months and six weeks respectively. The use of these different thyroid preparations in my case, one after another, shows that the failure is not attributable to inertness of the remedy.

CASE II. Mr. B., sixty-nine years of age, consulted me first March 26, 1893. He has had many attacks of rheumatic iritis, and been quite deaf for a number of years. He at first dated his symptoms from about December, declaring that he had been perfectly well the previous summer. Later he, and especially his wife, felt sure that the symptoms were of older date, and had been gradually coming on for at least a year, though more rapidly of late. He said he was suffering from "a dropsical tendency," and wished relief for two symptoms,—a nearly constant watering of the eyes and serous running from the nose, and an unsatisfactory condition of the bowels which moved once daily, the dejections being small and watery. I found that he was notably weak, so much so that he had not for some weeks made his accustomed daily visit to his club, only a few steps from the house. He had become very sensitive to cold, and would sit before the fire with his feet in a foot-muff and in a temperature of the room which was trying to his family. A sensation as if the lining membrane of his mouth and throat were swollen was also mentioned. Perspiration was absent. The skin of the hands was very dry and rough, the nails brittle; and he said his hands felt stiff when trying to grasp anything. The integument generally was dry and harsh, though far less so than the hands, and his skin had previously been unusually soft and smooth. There was pallor of the face and slight puffiness about the eyes and cheeks, suggestive of Bright's disease except for a translucency of the little folds and wrinkles revealed by close examination. The lips seemed swollen, and the lower was everted and somewhat pendulous. There was slight œdema of the ankles. His wife had noticed no mental change. Supraclavicular pads were not marked. In the median line of the neck, extending for perhaps two inches above the thyroid cartilage, was a scar, the result of an operation for the removal of a tumor by Dr. Hodges some twelve years ago. Dr. Hodges states that this was a deep-seated lipoma. The texture, color and thickness of the hair had shown no change; pulse 64; temperature 97.5; and the temperature was subnormal whenever taken during the few days which elapsed before treatment was begun. Physical examination, including the blood, gave negative results except as above stated and hæmoglobin 60 per cent. The urine was only 740 c. c. in twenty-four hours; specific gravity 1.020; albumen very faint trace; urea nineteen grammes to the litre; sugar absent; a few medium-sized hyaline casts and abnormal blood corpuscles.

The signs and symptoms seemed to me the same in

² British Medical Journal, August 27, 1892, p. 451.

character as those of myxœdema, though they were less in degree than in any case which I had ever seen or read of; and I had no hesitation in making this diagnosis, in which Dr. J. J. Putnam concurred. Dr. Putnam was so kind as to let me have some of Parke, Davis & Co.'s dried extract of thyroid gland, which had not yet been put on the market; and from April 1st to April 5th, inclusive, fifteen grains, the equivalent of one lobe of a sheep's thyroid, were given twice daily. April 6th, fifteen grains were given once. Before April 6th he complained of pains in the limbs and back. April 10th, seven and a half grains once. The remedy was then omitted until May 5th. After dinner on the evening of April 10th, I was sent for, and found him with severe pain in the cardiac region, resembling that of angina, with quick pulse and temperature slightly above normal. Morphia was given under the skin. For the next two to three weeks now he kept his bed. The attacks of pain tended to recur toward evening, and were always accompanied by marked increase in the pulse-rate, though irregularity and intermittency were never observed. With the subsidence of the pain, either spontaneously or after morphia, the rate promptly fell again. Nitroglycerine had no control over the pain. Repeated and most careful examination of the heart itself failed to detect any change in the size and sounds. He is a courageous man, whose iritic attacks have taught him what pain is, and he is reasonably tolerant of it; but this anginoid pain was so severe as to necessitate morphia hypodermically in one-half-grain doses. Two nights, at least, four of these were required to give relative comfort. The whole cardiac area was tender to pressure or touch, and a very limited spot just outside of the left nipple was exquisitely so. The necessity for hypodermics ceased April 28th. Gradually the attacks of pain diminished and disappeared; as did the tenderness, though more slowly. Meantime the myxœdematous symptoms showed marked improvement. The urine more than doubled in quantity, and April 13th was 1,028 specific gravity, with a very faint trace of albumen and forty-six grammes of urea to the litre, the sediment remaining the same. As he lay in bed now, he kept his arms out, covered only by his night-shirt, and desired only a sheet and one blanket as covering instead of a thick layer as before treatment. Desquamation took place as freely as after scarlet fever, affording the patient much occupation. The skin came off a toe like the finger of a glove. The watering of the eyes and running at the nose diminished materially. May 5th, one-grain doses of the extract every second day were given; May 18th to June 8th, one grain daily; June 9th to July 5th, two grains daily; from July 6th to the present time, four to eight grains daily. In June he felt better than for a year or two, in fact, perfectly well; and he has since so remained, though with the advent of cold weather the symptoms seem inclined to return in a measure. He has been remarkably free from headaches, to which he was formerly much subject. His weight has not varied materially.

CASE III. Mrs. C, thirty-four years old, consulted me at my office in March, 1898. Her family history was good, except that an uncle was ill for years with "deathly pallor and bloating." The catamenia appeared at fourteen and were regular until her marriage at twenty. Ten months later she was confined, and has never since been pregnant. The catamenia have

recurred every five to seven months, painlessly and otherwise normal in every way. For at least ten years she has been notably pale, more or less "bloated," sensitive to cold, perspiring but little if at all, better summers than winters. Six years ago she was operated on for laceration of the cervix, with some subsequent gain in strength. Her urine, she thinks, has not been scanty. She has been supposed to have Bright's disease. She thinks her memory is less good than it was, but recognizes no other mental change. The facies was strongly suggestive of nephritis, but the urine was negative. Unfortunately the urea was not quantitated. There was some swelling of the legs without distinct pitting. Visceral and blood examination gave negative results. The temperature was normal. The skin and its appendages were not notably changed except for swelling and pallor. Supraclavicular pads not marked. At her first visit I was not inclined to think her the subject of myxœdema; but was led to reconsider the diagnosis after my observation of Case II, which came to me soon after. I therefore sent for her and gave her at first seven and a half grains of the dried extract every third day, after three weeks every second day. There was no unfavorable symptom except some palpitation; later, pains in the limbs were complained of, but they passed off entirely. Improvement was prompt, and has been very marked. The swelling of her face and her girth diminished. There was desquamation of the skin and increase in strength. Early in June she reported that she perspired as she had not done for a long time, and said that all her friends were congratulating her on her changed appearance. One grain of the extract was ordered thrice daily, and this dose has been maintained ever since. I saw her a few days ago; and she then said that she felt better than for years, and has regained her natural shape, though her weight has gone up nearly twenty pounds. Her dressmaker states that her neck measures one-half inch less, her bust three and a half inches less, than last winter. The swelling of the legs has disappeared. The flesh in general has become natural in consistency; there is color in the lips and cheeks. She volunteered the statement that last winter she was not comfortable if the temperature of the room was less than 80°; and now she objects to a temperature above 65°.

CASE IV. Mr. D., of Missouri, visiting friends in the East, was sent to me by Dr. Gage of Lowell, November 17, 1898; fifty-two years of age, banker. Until five years ago his occupation was a very active one; since then has been sedentary. Family history, previous history and habits good. He never had malaria. For the past two years he has been less strong. The past two winters his hands especially have been very rough, and he has not perspired. Last winter and spring his friends began to notice a change in his color and appearance. Rest and change of scene was advised; but the panic came, and he had to stay at home. He lost his appetite; bowels became constipated; sexual desire was lost. He was weak, and very sensitive to cold. Some weeks ago he left home and went to some iron springs and then came East. He has gained fifteen pounds in flesh, with increased appetite and strength since leaving home; but his hands and appearance do not change. His eyes water easily, and his tear-ducts were dilated last summer with some relief. His former weight was 205; present, 180. The face presented a dirty pallor, with

slightly puffy and translucent lids; no swelling of the lips. The skin generally was harsh, especially the hands and feet. The hair dry; supraclavicular pads marked; temperature 96.5°; pulse 60; heart sounds weak, otherwise not remarkable; lungs and abdomen clear; knee-jerks present. Blood negative except for diminished hæmoglobin. No enlarged glands; no œdema of the legs; feet objectively very cold. November 17th, the daily amount of urine was about 40 ounces; specific gravity 1.015; an accident prevented the estimation of urea. November 24th, specific gravity 1.020. November 29th, specific gravity 1.025; albumen slightest possible trace; a few casts. December 6th, specific gravity 1.027; albumen slightest possible trace; an occasional hyaline cast. The patient reports a distinct increase in the flow of urine, but the amount has not again been measured. One grain of the thyroid extract twice daily was ordered, and November 29th four grains a day. November 29th, temperature 97.5°; less watering at eyes; sweat some yesterday after exertion. Some pain and tenderness on right elbow. Increased thyroid extract to six grains a day. December 6th, pulse 72; temperature 97.4°; skin about the same; color better; less sensitive to cold; eyes distinctly less watery; is less hoarse than for six months, and sang last Sunday for the first time during that period. The duration of treatment in this case has been very short; but its results confirm the diagnosis. I have learned to push the remedy cautiously.

Cases II, III and IV are unquestionably cases of myxœdema, and can be added to the rapidly lengthening list of cures. Dr. Kinnicutt³ collected 49 cases up to May 1st, treated by thyroid extract; and Dr. R. C. Cabot has kindly collected 68 cases published since May 1st. As before stated, two showed no gain under the treatment. Two of Dr. Murray's⁴ died suddenly while under treatment, the symptoms having markedly improved. One was known, the other suspected to have an unsound heart. Dr. Cabot has found two other fatal cases. In one diarrhœa set in after the first dose, and death was speedy. In the other,⁵ figured in Plate III, in Byrom Bramwell's "Atlas of Clinical Medicine," marked improvement in the myxœdematous symptoms had taken place. January 6, 1892, the patient had an attack of angina, took the last dose, and died seventeen days later. Myocarditis was found at the autopsy. In the 68 cases collected by Dr. Cabot the only other untoward symptoms which occurred often enough to make them especially suggestive were: faintness and headache in six cases, nausea and vomiting in four cases, pain in the back in four cases.

There has been so much written on this subject of late, and it is so prominently before the profession, that I shall not go into statistics or any general consideration of the disease and its symptoms; but there are several points illustrated by my cases to which I wish to ask your indulgent attention.

In the first place, we must recognize the fact, that, as in all other ailments, there are here differences of degree. Naturally the extreme cases were the first to be recognized, and to these alone does the description as now laid down in the text-books closely apply.

Total inactivity or loss of the gland is one thing; partial inactivity or loss another. It is highly probable that the latter does not necessarily lead to the former; at all events, a long period of years may elapse before the mild passes into the fully developed disease. The symptoms in Case III were of ten or twelve years' duration; and yet I at first crossed out myxœdema in my differential diagnosis. Now that our attention is awakened and we are on the lookout for cases, I am convinced that we shall find them to be pretty common. Case IV, the mildest I have seen, I am sure I should not have recognized a year ago, although I was then watching for cases. Case II illustrates the power of the remedy and the dangers of overdosage. Dr. Putnam and I decided on the initial dose in that case, as he had been giving that dose for some time to another, but an extreme, case with great benefit and no untoward result. The anginoid attacks caused me great anxiety. I can now see that it was unwise to fail to appreciate therapeutically differences in degree and duration, but I did not see it then. It may be said in extenuation that knowledge of the safe dosage of the remedy was then very slight and that experience had to be gained. Similar anginoid attacks have been noticed by other observers, and constitute the most important untoward symptom likely to be encountered during treatment. Pains in the limbs and back have also been noticed in some cases, and were complained of by Case II before the appearance of the anginoid pain. They were also present in Case III, and the pain and tenderness of one elbow in Case IV may be of neuritic nature.

It seems probable that the use of the remedy must be persisted in through life, and that larger doses will be required during the cold than during the hot weather.

Diagnosis should seldom offer any special difficulty at present. Grave anæmias and Bright's disease are readily excluded, as a rule. I say, "as a rule"; for we must not forget Starr's⁶ case, which had been diagnosed as Bright's by eminent authorities and so treated for years. But the albumen and casts disappeared entirely under thyroid extract.

SECOND ATTACKS OF TYPHOID FEVER IN ADULTS, TWO CASES.¹

BY A. L. MASON, M.D.,
Visiting Physician, Boston City Hospital.

OCCASIONALLY a patient with typhoid fever says that he has had it before; but on further inquiry this statement can rarely be verified, on account of the lapse of time and memory, and the absence of accurate data regarding the previous illness, the history, charts, etc. Therefore the two following cases, which came under my care during both the primary and the second attacks, with an interval of two years in each case, are recorded as being somewhat exceptional. In Case I, that of a nurse, it seems not improbable that the disease was conveyed to her directly by the patients she was nursing.

CASE I.—*First Attack.* Hospital nurse, aged twenty-four, after five days of prodromal malaise, September 7, 1890, was admitted to Dr. Rotch's service with typhoid fever. She came under my care October

it, in the later stages of a typical attack, which had been characterized by much abdominal pain and tympany, and was attended by a relapse, as is shown by the appended chart. During convalescence the pulse was high, 100 to 112, and she remained in hospital sixty-five days. (See Chart 1.)

CASE I.—Second Attack. October 10, 1892, the same patient was admitted to my service on the sixteenth day of her second attack. On the 23d of August she had gone to the country to nurse a patient with typhoid fever, and, after remaining there for a month in constant attendance, she contracted the disease herself. I saw her a few days later at home, when the symptoms were general malaise, insomnia, bad headache, fever and diarrhoea, but the knowledge of her severe attack two years before led me to doubt whether she had typhoid fever a second time. On admission to the hospital, rose-spots were abundant, the spleen was enlarged, anorexia and vomiting were troublesome. The urine was albuminous. The disease ran a longer course than before, defervescence taking place at the end of the fifth week, and the pulse then falling to 80. (Chart 2.) She got up on the fifty-seventh day, but from the sixty-fourth to the seventy-ninth day convalescence was interrupted by a recurrence of febrile symptoms and severe pain in the right iliac fossa, requiring morphia for relief. She left the hospital on the ninetieth day. (Chart 3.)

CASE II.—First Attack. A male cook, aged twenty-one, entered the service of Dr. Rotch, September 22, 1890. He had been ill ten days and complained of the usual prodromal symptoms of typhoid; malaise, pains in the limbs, headache, and nose-bleed. The bowels were constipated. In the second week splenic enlargement and rose-spots were noticeable; later the abdomen was swollen and tender. The fever abated at the end of the third week. As the patient appeared to be entering upon his convalescence, however, a relapse occurred which delayed his recovery for another month, and he remained in the hospital until the sixty-fourth day. (Chart 4.)

CASE II.—Second Attack. March 19, 1892, the same patient re-entered my service with a history of malaise and debility for the previous three weeks. He had lost his appetite, slept badly, and felt chilly and feverish by turns. Eight days before admission he gave up and went to bed. Epistaxis had been frequent. In the second week the symptoms were bronchitis, abdominal pain, splenic enlargement, and an abundant eruption of rose-spots. Diarrhoea ensued, with tympany; epistaxis recurred, and during the third week typhoidal stupor was very marked, as was also sensory deafness. There was no otitis. In the fourth week a laryngitis began and lasted two weeks. The right submaxillary gland became swollen to the size of an hen's egg, red and tender, but subsided without suppuration. During convalescence there was a peripheral neuritis affecting the feet and legs, and the patient was not discharged until the sixtieth day of his illness. There was no membrane in the throat at any time, and the laryngitis, glandular swellings, and neuritis were thought to be post-typhoidal. (Chart 5.)

Remarks.—The rare recurrence of typhoid fever in persons who are protected by a previous attack has been pointed out by many writers, but there is some difference of opinion as to the degree of immunity which is thus conveyed.

Nathan Smith, in his "Medical and Surgical Me-

moirs," says: "My own personal experience is strongly in favor of the non-liability of the same individual to a second attack of typhus; for during the twenty-five years since I first attended patients in this disease, and in that time I have visited many hundreds, and have witnessed its prevalence several times in the same village, I have never known nor heard of its recurrence in the same person."

This accords with the researches of Gendron in his "*Mémoire sur les épidémies des petites localités.*"² He mentions several instances of this immunity, among them the following: The village of Petit-Gênes had fifteen inhabitants, of whom twelve had typhoid fever. Of the three others two had had it before. Three years later, in a second epidemic, the disease attacked five persons only, who had come there since the previous outbreak.

Chomel, at the Hôtel Dieu, among one hundred and thirty typhoid patients, found no one who had previously had the disease.

On the other hand, Alonzo Clark, in his "*Lectures on Fevers,*"³ mentions two epidemics of typhoid as occurring in Richmond, Massachusetts, in which Dr. Jennings attended two patients with second attacks, of whom he had also taken care during their fevers two years before. Sixty persons were attacked in each epidemic, but no details of these cases are given.

Piedvache⁴ relates the case of a girl who had a severe attack at the age of ten, and a second one eight years later. Michel⁵ had met with three cases; and Paul,⁶ one in which a second attack occurred after three years.

Trousseau,⁷ with his long hospital experience, saw but one case at the Hôtel Dieu, where a woman under his care had typhoid four years after an attack of the same disease in the wards of Professor Rostan, where she had remained four months. Trousseau in his private practice also met with one case: a girl twelve years old took typhoid fever in a severe form. The illness lasted fifty-seven days. In the following year she had another characteristic attack fifty days in duration.

Liebermeister⁸ says that this disease confers a certain immunity, but not as complete as is the case with variola, measles and scarlet fever. He alludes to recurrent cases at the Basle Hospital, but gives no details.

Murchison (third edition, 1884) says: "It is generally believed that one attack of enteric fever confers an immunity from subsequent attacks." After recounting in brief the observations of Gendron, Piedvache, Bartlett, and others above-mentioned, he states that several cases had come under his notice in which two attacks had occurred in the same person after puberty, and that four similar cases were observed by Dr. William Budd (1859).

Strümpell's opinion (American edition, p. 4) is that "it does seem to be certain that the occurrence of typhoid fever gives very probable though not absolute immunity against any later new attack."

Pepper, in "The American Text-Book of Theory and Practice,"⁹ states that he has attended several patients through two characteristic attacks of typhoid

fever, and has had more than one apparently reliable account of three distinct attacks at intervals of several years. The same author says that a study of six hundred cases by Eichhorst showed the occurrence of a second attack twenty-eight times, or in 4.7 per cent.; and that recurrences are more common in men than in women, and milder than the original attacks.

Moore, of Dublin, in his recent work on "Eruptive and Continued Fevers,"¹⁰ gives a "Case of Recurrent Enteric Fever followed by Relapse," in full detail, with charts of both attacks, and also contributes a report of the same case to the *Dublin Journal of Medical Science*, April, 1892.

From the foregoing citations and cases, it appears probable that physicians who see many cases of typhoid fever may, in the course of years, meet with a few recurrent attacks in their own practice. Therefore I made inquiry on this point of most of my past and present colleagues at the City Hospital, who have all had exceptionally large experience in this disease. The mere statements of patients that they had had typhoid fever more than once were not regarded as sufficiently conclusive, but cases corroborated by records, charts, or the remembrance of professional observation, were sought for. None were found.

Dr. Robert T. Edes, who paid much attention to this disease, and whose paper on "The Cold Water Treatment of Typhoid Fever," by bathing, appeared in the *City Hospital Reports*, Second Series, 1877, replied to my inquiry as follows: "I do not think I ever saw a case of typhoid fever in a person who, to my knowledge, had had it some months or years before."

Dr. C. Ellery Stedman, whose published "Notes on Typhoid," based on an analysis of 1,188 cases at the City Hospital, are contained in the "Reports," Third Series, 1882, answered that he had "formed the opinion that one seldom had the fever, *really*, twice." He had no proofs of recurrent attacks, in the way of charts and records.

Dr. C. F. Folsom writes: "I have never seen recurrent typhoid fever which I knew to be such. A few patients stated that they were suffering from second or recurrent attacks."

Dr. T. M. Rotch says: "I do not recollect any cases of recurrent typhoid."

Replies of similar tenor were received from Drs. J. G. Blake, Geo. B. Shattuck, E. J. Forster, and other members of the hospital staff with long experience. In an analysis of 676 cases of typhoid admitted to the hospital in 1890 and 1891, after careful examination of the records, I found no recurrent cases.¹¹

Therefore the two instances recorded above, with their histories and charts, are the only ones I have been able to verify, as having occurred in this hospital, in which the same patient has been admitted twice for typhoid fever. One other case came within my own knowledge in which a recurrent attack was fatal after an interval of thirty years.

Although the negative results of such an inquiry must be to some degree inconclusive, and a few authenticated cases indicate the probability of a still greater number which fail of positive proof, I think it may be assumed that the immunity afforded by an attack of typhoid fever is as complete as in the case of the exanthemata, except, perhaps, small-pox, in which it is said

that less than one per cent. of recurrences occur,¹² although Sir Thomas Watson states that a few instances are recorded of three attacks of this disease in the same person.¹³

A BACTERIOLOGICAL STUDY OF FOUR HUNDRED CASES OF INFLAMMATION OF THE THROAT, OCCURRING IN DIPHTHERIA AND SCARLET FEVER, WITH ESPECIAL REFERENCE TO PATHOGENESIS.¹

BY JOHN LOVETT MORSE, A.M., M.D.

(Concluded from No. 7, page 156.)

MIXED INFECTIONS.

The pseudo-membranous inflammations of the throat occurring in scarlet fever are always accompanied by cocci, usually streptococci. The presence of the Klebs-Löffler bacillus, means association with diphtheria as the result of a mixed infection. Janson (28) in seventeen cases of scarlet fever found streptococci alone or associated with other cocci. Baginsky (11) did not find the Klebs-Löffler bacillus in scarlet fever, and thinks that it disappears in cases of diphtheria when an eruption similar to the scarlatinal fever is developed and gives place to cocci. Park (13) found streptococci in seventeen cases of scarlet fever, and Sorenson (18) in thirteen cases of scarlatinal diphtheria found cocci and other organisms, but never Klebs-Löffler bacilli. Booker (19) has made a special study of the forms of cocci found in the scarlatinal pseudo-membranous angina, but does not find the Klebs-Löffler bacillus in them. Escherich and Bourges, however, have found them in the throat affections appearing in the course of scarlet fever.

In ninety-nine cases of scarlet fever with simultaneous pseudo-membranous inflammation of the throat, the following bacteria were found:

	Cases.
Klebs-Löffler bacilli alone	3
K. L. and streptococci	1
K. L. and staphylococci	10
K. L. and streptococci and staphylococci	9
Streptococci alone	4
Staphylococci alone	12
Streptococci and staphylococci	23
Streptococci, staphylococci and others	34
Other bacteria	3

That is, there were twenty-three cases of mixed infection, or nearly twenty-five per cent. Streptococci were present, alone or associated, in seventy-one cases, or in seventy-one per cent.

This tremendous proportion of cases of mixed infection can be accounted for in a number of ways. In the first place, the scarlet fever and diphtheria wards, although isolated from the rest of the hospital, are in charge of the same house-officers and visiting physicians. They are constantly going from one ward to another, and, although always wearing gowns in the wards and disinfecting their hands on leaving a ward, are probably responsible for a large number of the mixed forms. Various other persons, not directly connected with the care of the patients, also enter both

wards. The possibility of the direct infection with Klebs-Löffler bacillus by physicians, nurses, and convalescent patients must also be considered, as it is undoubtedly a fact that a person with a very slight sore throat, without visible membrane, due nevertheless to the Klebs-Löffler bacillus, may infect others with a severe form of the disease. It is also a fact that the bacillus remains for a long time in the throats of convalescent patients, retaining its virulence, and rendering them a source of danger to others. Escherich (17) found the virulent diphtheria bacilli in cases in which the clinical picture of diphtheria was wanting. He thinks that these persons are immune towards the toxin, while there is no limitation to the growth of the bacillus. In one case a nurse in a hospital had the bacilli in her throat and, without being diseased herself, gave the disease to the children intrusted to her care. Feer (20) reports five cases in children in which the diphtheria bacilli were found on the tonsils without there being a trace of membrane. Koplick (14) has also proven the existence of similar cases. A certain number enter the hospital with a mixed infection, as is shown by bacteriological examination. As there is at present no separate ward for such cases, they are necessarily placed in one of the present wards. Although they are isolated as far as possible in separate rooms, they are undoubtedly the source of a certain number of other mixed cases. I think, moreover, that the diagnosis of scarlet fever is often made on insufficient grounds. The existence of scarlatiniform rashes and erythema fugax in diphtheria is well recognized (21 and 22). Steam and rough clothing next to the skin are also very likely to cause an erythema, which is often quite lasting. Drug exanthems may also give rise to error. These mistakes in diagnosis are especially liable to occur in cases which survive but a short time, thus not allowing opportunity for the recognition of the fleeting nature of the eruption. That these mixed cases do originate in the hospital is shown by the fact that during the period covered by this study sixteen cases developed scarlet fever in the hospital at an average time of nearly two weeks after entrance. Moreover, seven cases of scarlet fever developed inflamed throats during convalescence, in all of which the Klebs-Löffler bacilli were then demonstrated, although they had been absent previously. Under the present conditions these secondary infections are unavoidable, although every possible precaution is taken to prevent them. With the completion of the new wards for contagious diseases, however, which are now in process of erection, the conditions will be radically improved and all opportunity for such cases removed.

BACTERIA OF THE HUMAN MOUTH.

Very extended researches (34) have been made with reference to the bacteria in the human mouth, which show that numerous species are constantly present in the buccal secretions and upon the surface of the moist mucous membrane. Some are occasional and accidental, while others appear to have their normal habitat in the mouth, where the conditions as to warmth, moisture, and organic matter are extremely favorable for their development. Up to the year 1885 Professor Miller, of Berlin, had isolated twenty-two different species from the human mouth—ten were cocci; five short bacilli; six long bacilli, and one a spirillum. He later cultivated eight additional species. Vignal has isolated and described seventeen

species obtained by him in pure culture from the healthy human mouth; most of them are bacilli. Miller, who found micrococci to be the more numerous, supposes the difference in results to be due to the fact that many of the cocci do not grow on nutrient gelatine, which was the medium employed by Vignal.

Among the species we find two of the most common pus cocci, namely: the staphylococcus albus and aureus. Very different results have been reported by different observers as to the frequency with which these pathogenic cocci are found in the buccal cavity. Black, in the saliva of ten healthy individuals, found the staphylococcus pyogenes aureus seven times, the staphylococcus albus four times, and the streptococcus pyogenes three times. On the other hand, Netter found the staphylococcus aureus only seven times out of one hundred and twenty-seven persons examined. Vignal, in the course of his researches, did not find the streptococcus pyogenes at all. Experiments made by Sternberg, Vulpian, Fraenkel, Netter, and others, show that the diplococcus pneumoniae is frequently present in the mouths of healthy individuals. Netter found it in fifteen per cent. of one hundred and sixty-five cases. Several other species have also been isolated by late observers. Sanarelli has also shown that the normal saliva has the power to destroy the vitality of a limited number of certain pathogenic bacteria, among them the staphylococcus aureus and streptococcus pyogenes.

RELATIVE FREQUENCY OF MICRO-ORGANISMS.

The small number of organisms found in the course of this study is probably because many do not grow on the media employed, and because others do not develop in the short time allowed before the cultures are examined.

The organisms most commonly met with, either alone or associated with the Klebs-Löffler bacilli, were streptococci and staphylococci. Diplococci were found in a number of cases and various forms of bacilli met with from time to time.

Streptococci occurred in 191 cases	48%
Staphylococci occurred in 226 cases	74
Diplococci occurred in 54 cases	13
Bacilli occurred in 87 cases	22

MORTALITY.

In this routine work no attempt was made to determine the nature of these bacilli, although several of them were carefully worked out in a shorter series to be reported later. The diplococcus lanceolatus was also noted in nine cases. As has already been stated, the mortality in cases containing the Klebs-Löffler bacillus was forty-one per cent. against twenty-three per cent. in cases in which it was absent. How the mortality was influenced by the presence or association of the various bacteria is shown in the following table:

K. L. alone in 46, of which 20 died	43%
K. L. with streptococci in 21, of which 6 died	28
K. L. with staphylococci in 93, of which 43 died	46
K. L. with streptococci and staphylococci in 77, of which 29 died	38
K. L. with others in 3, of which 1 died	33
Streptococci alone in 18, of which 1 died	5
Staphylococci alone in 27, of which 15 died	40
Staphylococci and streptococci 99, of which 19 died	19
Others in 5, of which 2 died	40

These figures show that the mortality is about twice

as great in those pseudo-membranous inflammations of the throat in which the Klebs-Löffler bacillus is present as in those in which it is absent. They also show that the mortality is not appreciably altered by the presence of other bacteria in association with the diphtheria bacillus. This result is somewhat at variance with those obtained by other investigators, several of whom have done special work with regard to the influence of other bacteria on the virulence of the Klebs-Löffler bacillus. Roux and Yersin (27) made injection experiments on guinea-pigs with mixed cultures of Löffler's bacillus and erysipelas. The animals experimented on died in forty-eight hours, while other guinea-pigs, which were inoculated with pure cultures of the same diphtheria bacillus, did not die. They also found certain products in mixed cultures which were not present in the pure cultures of either organism.

The toxic albumens obtained from the mixed cultures were much more virulent than those from the pure. Those of pure cultures of diphtheria bacilli killed guinea-pigs in thirty-six hours, while those from mixed cultures killed them in ten hours. Janson (28) thinks that the prognosis is worse when the bacilli are associated with a streptococcus. Heubner (15) found that sixty-six per cent. of the cases in which the bacilli were found alone died, and fifty-five per cent. of those in which they were associated with other cocci. Martin (23) found that in all cases of diphtheria where the streptococci were present there was a more fatal course than in those where only simple forms of cocci were found. He thinks that the presence of streptococci, either with or without the bacillus, materially complicates the prognosis. Goldscheider (24) found that the cases in which streptococci were present ran a more severe course, and lasted longer, and thinks that they may play a very important rôle in diphtheria. Gottstein (25) thinks that the streptococcus symbiosis may cause an increase in the virulence of the bacilli. Barbier (26) thinks that the diphtheritic infection may have a much more malignant character when it is engrafted on a streptococcus inflammation. He is inclined to believe that there are two forms of diphtheria to be separated from one another, one the pure form, and the other mixed with streptococcus. The latter corresponds to the form which is known as septic diphtheria.

The general opinion thus seems to be that other organisms, especially streptococci, in connection with the Klebs-Löffler bacillus, render the prognosis more grave. It would seem from my figures, however, that they have little or no influence. It would also seem that staphylococci, either alone or in combination, were more fatal than streptococci.

A series of twenty-five cases, uncomplicated by scarlet fever and containing the Klebs-Löffler bacillus, were examined more carefully. Agar plates were made from the first slant tube of blood serum, and all the organisms present isolated in pure cultures. Pure cultures of all the Klebs-Löffler bacilli were obtained upon blood serum, of the streptococci on glycerine agar, and of the staphylococci on blood serum or agar. The staphylococci were also further differentiated by growth and liquefaction in gelatine stick cultures. The other organisms met with were studied as to their cultural peculiarities on the various media and inoculated into animals. The following table shows the results obtained:

No.	Name.	Diag.	Bacteria.	Result.

(1) Bacillus Coli Communis.

Diagnosis made on following peculiarities: Short, thick bacillus with rounded ends, often resembling a coccus. Acidified and coagulated litmus milk. Formed gas in sugar agar. Did not liquefy gelatine. Gave moist, distinct, yellowish growth on potato. Slightly motile in hanging drop of bouillon culture. Gave indol reaction in Dunham's solution.

(2) Diplo-Bacillus.

A diplo-bacillus with lancet-shaped ends. Morphologically always the same. Stains readily with the aniline dyes. Grows freely in white colonies on blood serum and glycerine agar. No growth in gelatine. Invisible growth on potato. Does not form gas in sugar agar. Does not coagulate or acidulate litmus milk. Whitish growth at bottom of bouillon. Non-motile in hanging drop of bouillon culture. Non-pathogenic for guinea-pigs. Resembles more nearly the bacillus septicus acuminatus of Babes than any other, but is probably not the same. Was found in two cases of this short series and observed a good many times in the long series, although its cultural characteristics were not studied at that time.

(3) Large Diplococcus.

Colonies on agar plates. White, homogeneously granular, with well-defined edges. Grows rapidly. Profuse white growth on glycerine agar; removed from surface with difficulty. Grows freely on blood serum. No growth in gelatine. Slow growth at bottom of bouillon. Non-motile in hanging drop of bouillon culture. No growth on potato. Non-pathogenic for guinea-pigs.

(4) Short Bacillus.

A small bacillus, not forming spores. Stains with aniline colors. On gelatine plates deep colonies show coarsely-granular, sharply-defined centre with finely-granular, outer layer having well-defined border. Liquefy plates in 24°-48°. Stick cultures in gelatine tubes show profuse white growth, liquefying surface and extending in pyramidal shape downward. Profuse growth on blood serum which it liquefies. Moist, yellowish growth on potato. Profuse white growth on surface of sugar agar, but no gas formation in stick culture. Gives marked white cloudiness in bouillon culture, and after a few days forms a white pellicle on surface. Motile in hanging drop of bouillon culture.

Does not coagulate or acidify litmus milk. Profuse creamy-colored growth on glycerine agar. Non-pathogenic for guinea-pigs.

These two last forms do not correspond to any described by Sternberg. This may be either because they have not been met with before, or if so, imperfectly described.

Of course, statistics compiled from so small a number of cases are of little value, but I nevertheless give them for what they are worth.

Klebs-Löffler bacillus not found alone.

Streptococci in 19	76%
Staphylococci in 10	40
K. L. and streptococci in 9	36
K. L. and staphylococci in 4	16
K. L., streptococci and staphylococci in 6	24
General mortality	56
Mortality, K. L. with streptococci alone	33
" K. L. with staphylococci alone	66
" K. L. with streptococci and staphylococci	66

Thus this series, as far as it goes, also seems to prove that staphylococci are more fatal in combination with the Klebs-Löffler bacilli than streptococci. It must be remembered, however, that in both series bacteriological results have alone been considered. It is very probable that an explanation for this excessive mortality in connection with the staphylococci would be found in the other pathological conditions, other factors, possibly severe lung complications, being present to account for the fatal termination.

Streptococci were present in a much larger proportion of cases than in the longer series. This result is, however, probably more correct, for in the routine examination mistakes were liable to arise in two ways. Streptococci, on account of their slower and smaller growth, were probably missed in some cases, and in others called staphylococci because they were bunched, it often being impossible to differentiate the two forms when closely crowded on a cover-slip.

VIABILITY OF KLEBS-LÖFFLER BACILLUS. — PERIOD OF CONTAGIOUSNESS.

Investigations were begun as to the length of time that the Klebs-Löffler bacilli remained in the throat after it was apparently clean. Patients are not now allowed to leave the hospital until the bacilli have disappeared from both throat and nose, as shown by bacteriological examination. The results of the examinations in the first twenty-five cases is appended. Considerable work has recently been done in this direction by several investigators. Janson (28) found the bacilli fourteen days, and Haubner (15) ten days after the membrane had disappeared from the throat. Tobiesen (30) examined the throats of forty-six patients, who left the hospital as well, for diphtheria bacilli. They were found in twenty-four cases, the length of time which they persisted bearing no relation to the previous severity of the case. They were found eight times four days after the membrane had vanished; three times, five days after; three times, seven days after; three, nine days after; one, eleven days after; one, fourteen days after; one, fifteen days after; one, seventeen days after; and one, thirty-one days after. These patients did not present any other pathological condition. He thinks that the presence of bacilli in the pharynx is assisted by pathological conditions of the larynx and nose. This late bacillus had the same pathogenic influence, on the inoculation of guinea-pigs, as the others. He regards it as possible that half the

patients who leave a hospital, after having had diphtheria, have the power to infect their surroundings with the disease. He found one case who, after leaving the hospital, was certainly the source of infection for others. Löffler (31) investigated one case daily as to the presence of diphtheria bacilli. The fever disappeared on the fifth day, and the throat lesions on the sixteenth day. The bacilli, however, remained for four weeks longer. Verstraeten (32) also found the bacilli four weeks after the membrane had disappeared and Roux and Yersin (27) found them in virulent condition fourteen days after the membrane had vanished.

In my cases it was found that the average length of time that the Klebs-Löffler bacillus remained in the throat or nose after the membrane had disappeared was ten days. The average duration was the same for both throat and nose, although in some cases the bacilli were found in the throat much longer than in the nose, and *vice versa*. The bacilli disappeared in one case the day after the throat was clear; in three, three days after, and in one, four days after. In two cases in which the bacilli were never found in the nose, they remained in the throat ten and seventeen days respectively. In other cases, they were present in the throat thirty-seven days, and in the nose thirty-six days; in the throat twenty-two days and nose eighteen days; in throat ten days and nose seventeen days; and in both twenty-seven days. In order to test the virulence of these late bacilli, a guinea-pig was inoculated with a pure culture of the bacillus obtained from a throat which had been perfectly clear for ten days. It died on the third day, and the Klebs-Löffler bacillus was recovered from the seat of inoculation.

PSEUDO-DIPHTHERITIC BACILLUS.

The so-called pseudo-diphtheritic bacillus was not considered in this series, as the diagnosis was usually made entirely on morphology, and the cultural and pathogenic properties of the bacilli rarely studied. So much has been written about this organism, however, that it deserves consideration. The evidence is very contradictory, however, and the question of its existence must still be regarded as unsettled. Hoffmann (16) finds that this bacillus is a frequent and apparently regular inhabitant of the pharynx, and that it agrees very closely in its morphology and physiology with the Klebs-Löffler bacillus, but is non-virulent. He says that certain definite morphological differences may be made out on careful comparison with the Klebs-Löffler bacillus, but fails to state them clearly. Escherich (17) thinks that the diphtheria bacillus has in bouillon cultures a greater tendency to arrange itself in parallel masses, while the pseudo-bacillus lies in irregular groups. In the pseudo-bacillus there is a brown color on old agar cultures which never occurs on diphtheria cultures. He regards as the most distinctive point the growth in litmus bouillon, which at first remains violet and then becomes red. Diphtheria cultures produce this more rapidly. By inoculations of guinea-pigs, no immunity could be produced. According to his investigations, the pseudo-bacillus has been found only thirteen times in three hundred and twenty cases. Fraenkel (33) thinks that it is the true bacillus which loses its virulence on artificial media, just as the pneumococcus does. Roux and Fraenkel consider the two bacilli identical, and that the only difference is one of virulence. Roux and Yersin (27) found that the only difference between these forms appears to be that the

false bacillus is found shorter on serum, that it develops more abundantly in bouillon, and continues to grow at twenty to twenty-two, while the virulent one grows only slowly. The change in the reaction of the bouillon takes place less quickly in the pseudo-diphtheritic than in the diphtheritic. They sought for this pseudo-form in forty-five sound children, and found it in fifteen. They also found it in the throats of twenty-six children out of fifty-nine in a village where there was no diphtheria. It was always present in small numbers. The inoculation of this bacillus never produced fatal consequences; at the most, only a local oedema. They succeeded in various ways in diminishing the virulence of cultures of the virulent bacilli. The non-virulent organism thus produced compared fully with the pseudo-diphtheritic bacillus. These pseudo and non-virulent forms did not produce any toxins. In some cases, also, it was possible to increase the virulence of the organisms. The virulence was increased when the guinea-pig was inoculated with an active erysipelas culture at the same time. Neither the weakened bacillus nor the streptococcus alone could produce the death of the animal, but the mixed cultures could. Death took place with the phenomena of diphtheria, and the diphtheritic bacilli underwent an increase of virulence. The weight of evidence at present thus seems to show that the organisms are the same, differing only in virulence. Further work is necessary, however, before the question can be definitely settled.

RESULTS.

The results obtained from the study of this large number of cases are not as valuable as they would be if the clinical side was considered in connection with the bacteriological. It is probable, for example, that the mortality apparently due to staphylococci would be to a certain extent explained by a careful examination of the cases clinically. The relation of the operative cases to the bacteria present is also important. There would be great danger, however, of detracting from the value of the results as a whole, if too many factors were considered. It is unfortunate, also, that the fatal cases could not have been autopsied, as an accurate knowledge of the pathological and bacteriological conditions would be invaluable. It is extremely difficult, however, to obtain autopsies in Boston, and in no case more so than in that of a contagious disease. It is to be hoped, nevertheless, that they may be obtained in the future and this vast amount of material utilized, for here lies the field for conclusively demonstrating the results of the symbiosis of other forms of bacteria with the Klebs-Löffler bacillus.

RECURRENT APPENDICITIS.¹

BY ALBERT AUGUST, M.D., CAMBRIDGE, MASS.

THE subject of this paper is a young man, age twenty-three years, single, student. Born and lives in Cambridge. Family history negative. Has always been well until he had typhoid fever three years ago, from which he entirely recovered, but has been troubled with chronic constipation since.

His first attack of appendicitis was January 1, 1892, when he complained of pain across the lower part of the abdomen, not very acute, but with considerable soreness; bowels were constipated. He entered the Cambridge Hospital at this time, and the record of the examination showed him to be of fair nutrition, pale and nervous, tongue coated with a pasty white coat. There was general tenderness over the abdomen, but it was especially tender in the right and left iliac regions. No dullness on percussion except in hypogastrium, due to a distended bladder, for the relief of which the catheter was used. The treatment at this time consisted of morphia suppositories, sufficient to keep him comfortable, and flaxseed poultices over the abdomen.

January 2d, the record shows some resistance in the right iliac region, with considerable sensitiveness on superficial pressure. Bowels were flat. I will say here that our patient was extremely hyperæsthetic.

January 4th, the tenderness over the abdomen had considerably diminished. Area of dullness had decreased in the right iliac region. Bowels were moved by enema. As our patient continued to improve, the tenderness became more distinctly confined to the area of the appendix.

He was discharged well January 14, 1892, having been in the hospital thirteen days. After he left the hospital he improved gradually, and at the end of a few weeks he was able to resume his college work.

His next attack was February 14, 1893, a little over a year since the first. He had been feeling poorly for five days, due to constipation, for which he took compound licorice powder. On the 18th he went to an evening party, and on his return home began to vomit, and complained of considerable pain in the abdomen.

He entered the hospital February 16th, where the recorded examination showed much tenderness in the right iliac region. The point of extreme pain was just

¹ Read before the Cambridge Society for Medical Improvement.

below a line drawn from the anterior superior spine to the umbilicus; the tender area was about two inches long, and one and one-half inches wide, with the internal border about three-quarters of an inch to the right of the median line. His general and local condition constantly improved after entering the hospital, so that he was discharged on March 2d with only slight resistance in the right iliac region, but no dulness on percussion.

The third attack occurred April 14, 1893, an interval of a little over a month, and again after dancing at a party. He went to bed feeling perfectly well, but awoke early in the morning with severe pain in the bowels, most marked in the right iliac region. He entered the hospital on that same afternoon. Examination showed the bowels to be flat; on pressure, there was slight resistance over same area as described in previous attack, with the greatest tenderness confined to this region. Examination of urine showed it to be normal.

A consultation of the hospital staff was held at this time with reference to surgical interference, but it was decided to wait and advise operation during an interval between the attacks.

He steadily improved with a diminution of the resistance in the right iliac region and disappearance of the pain, and was discharged well March 22d.

Our patient gradually improved, but not wholly. He became very pale and anæmic, was extremely nervous and irritable, and was obliged to give up his college work. He was unable to take any immoderate exercise, on account of soreness and a feeling of stiffness in his right side; and if any one accidentally came in contact with him here, it would cause him considerable pain. His general condition became extremely erratic now. One day he felt perfectly well, and would indulge either in a day's work or amusement, for which he would pay the penalty on the next by being overcome with a sense of weariness and inability for any unusual exertion; in other words, he was reduced to the state of semi-invalidism, so much so that in the latter part of July, I urged him to take a journey into the country, to see what a change of air might do for his general condition. He had grown extremely nervous about himself, and was in constant fear of another attack.

On the 24th of July last, he went to New London, N. H.; and while there he indulged in considerable exercise — base-ball and riding (or rather jolting) over the New Hampshire roads, etc.

On the 26th of July he began to feel ill; and on the evening of that day he was seized with extreme pain in the right iliac region, and vomited considerably. They had no morphia to give him, and he suffered extreme agonies; the only relief he obtained was by frequent applications of hot poultices. In this way they brought him through the night, and until they were able to procure some morphia for him on the next morning.

I saw him in New London, July 28th, with a temperature of 102.5°, and pulse 120; he had not passed water for eighteen hours, and on his countenance was a very anxious expression. The abdomen was flat; in the right iliac region there was considerable dulness, with the tenderness well marked at McBurney's point; and the general condition was like that of his three previous attacks. By means of rest, poultices, and morphia sufficient to control his pain, we were

able to bring him home, August 3d, when he began to improve again to a certain extent.

About a week later, August 11th, after running for a train, he was seized with another attack, very slight, which confined him to his bed for four days only.

He was now tired of Damocles' sword, and readily acquiesced when relief was offered to him by surgical means.

He entered the Massachusetts General Hospital August 23, 1893. The operation was performed by Dr. A. T. Cabot, August 26th, the patient having been previously carefully prepared. On the day previous to the operation, he was allowed no solid food; his bowels were well moved with castor-oil; and an enema, with turpentine, was administered. On the morning of the operation he was thoroughly bathed, and an antiseptic poultice placed over the abdomen.

Operation. — Patient was anæsthetized, ether being used. An incision was made over McBurney's point, about four and one-half inches long, the general direction corresponding to the outer border of the rectus muscle. Passing the fingers into the peritoneal cavity, the appendix was found in a bed of very firm adhesions, attached to the anterior abdominal wall. Adhesions were separated with the fingers, and the appendix was liberated and brought up into view at the opening. The appendix was surrounded with adhesive inflammatory products, from which it was freed. Hæmorrhage from a small artery on the external surface of the appendix persisted, and the artery was tied. A silk ligature was now passed around the base of the appendix; a cuff of the peritoneal coat of the appendix was dissected back; the appendix was cut off; and the peritoneal cuff was stitched over the stump with silk. The stump was turned toward the right side of the abdominal cavity. The abdominal wound was brought together by means of six silk-worm-gut ligatures, which were passed through all the layers of the abdominal wall; the wound was sewed up tight, no drainage being used.

Macroscopic examination of the appendix showed it to be two and one-half inches long, with the walls somewhat thickened; at the end and on one side it was perforated, but the surrounding parts were protected by the inflammatory products. The lumen was pervious, and no concretion found. I have not received the report of the microscopic examination.

He made a good recovery from the ether, and made a progressive convalescence. His temperature was practically normal throughout; his bowels were moved August 28th with calomel and one seidlitz powder, and thereafter moved voluntarily. On account of the unusual length of the incision, the stitches were not removed until the twelfth day, when everything was found firmly united. He walked out from the hospital well, September 11th, sixteen days after the operation. Since leaving the hospital, he has steadily improved, both in weight and general condition. He has lost that nervous irritability to a great extent, and has regained his former ambition. He is now able to go in town every day, and do a day's work without any of the former fatigue. I saw him recently, and examination of the right iliac fossa revealed no tenderness or resistance whatever.

The particular etiology of appendicitis is still somewhat obscure, that is, we have no definite set of predisposing causes which we can be sure are the origin of the trouble. Some writers speak of constipation as

a *sine qua non*; others suppose that diarrhoea plays an important part; still others think that it is caused by the impaction of a foreign body; and Treves considers a short mesentery as an important etiological factor, and a consequent twisting of the appendix as a result of this.

Constipation seems rather coincident than etiological. In 209 cases analyzed by R. H. Fitz, only 38 had an antecedent history of constipation; while Talamon points out that the most obstinate cases of constipation are in women, and still appendicitis is four times as common in males as in females. Again, we have constipation the rule in people of advanced age; and we all know that the greatest number of cases of appendicitis occurs between the ages of fifteen and thirty years.

Treves says that faecal concretions are not commonly found; Matterstack found only nine cases in a series of 146. Talamon suggests that a considerable proportion of cases are caused by faecal concretions, those not being found at operation having possibly been forced back by the muscular contractions of the appendix, or if an abscess has formed with perforation, that the faecal concretion has become softened and disintegrated by the action of the pus.

I have been much interested in Dr. Talamon's theory as regards the predisposing cause. He suggests the existence of a membranous colitis, or intestinal atony, where the patient has uncomfortable, distressing pains in the bowels, irregular stools, sometimes mucoid and sometimes constipated, and that the faecal and mucoid matters are deposited in the cul-de-sacs of the mucosa and are dried, and under favorable conditions (for example, increased peristalsis) are forced into the lumen of the appendix. He considers this to be the primary cause in recurrent attacks, which causes a peri-appendicitis and consequent adhesive inflammation about the appendix which binds it at an acute angle to the caecum, as in the subject of this paper, where the appendix was bound down firmly to the anterior abdominal wall in such a manner that all fluids or solids were forced into the caecum against the action of gravity. It is very easy to see how the appendix may become distended with fluids under these conditions, and how congestion and ulceration may follow.

Dr. Cabot has noticed in almost all of his operations for recurrent appendicitis that the appendix was bound down by adhesions in such a manner as to twist the lumen of the appendix out of its proper relations.

Dr. W. T. Bull, in the *New York Medical Record* of March 18, 1893, describes twelve cases in which he also noticed the appendix sharply bent and fastened in that position by adhesions.

In some cases, the tip of the appendix had been imbedded in a small abscess-cavity, which remained latent only to light up and cause a recurrence at the slightest occasion.

Fitz states that attacks of indigestion and acts of violence, especially from lifting, jumping and pulling, are exciting causes in one-fifth of the cases. A local cause is found in more than three-fifths of all cases, for example, inspissated faecal matters, or the presence of a foreign body.

The question of the propriety of operating in the interval between the attacks is an open one, and must be considered in each individual case. Dr. Fitz, in his statistics, places the percentage of recurrence at 11 per cent. Dr. S. F. Dennis thinks that conservatism

should be used in operating, since only 11 per cent. of the cases are recurrent, and of these some end in resolution, or else the lumen of the appendix is ablated by chronic inflammation, and is reduced to a thickened fibrous cord. In some cases, he says, the perforation will cause an extra-peritoneal abscess; and in still others there will be a localized, circumscribed, intra-peritoneal abscess, which may empty itself by rupturing into the rectum, vagina, caecum or bladder; and that only a small percentage of dangerous cases would be left, and he thinks these might be operated on early in the next attack.

Treves first advised the operation in 1877, and considers that the following indications justify it: (1) If the attacks have been very numerous; (2) if the attacks are increasing in frequency and in severity; (3) if last attack has been so severe as to place the patient's life in considerable danger; (4) if the constant recurrences have reduced the patient to a condition of chronic invalidism, and has rendered him unfit for occupation; (5) if owing to persistence of certain local symptoms during the quiescent state, there is a probability of a collection of pus.

As regards the mortality of the operation. In a collection of 81 cases by Cabot, there has been only one death, which was due to sepsis, a mortality of about $1\frac{1}{2}$ per cent. Treves reports 14 cases operated upon, all of which made a sound recovery.

It seems to me that if an operation is inevitable, the sooner it is done the better, that is, before the patient has had too many recurrences; for then there is a liability that the adhesions are dense and firm, and very difficult of separation.

Some writers say that there is no necessity of alarm in recurrent attacks, for nature protects herself against general infection of the peritoneum by these very adhesions which are formed, and that general peritonitis is avoided. Still, Price has collected 30 cases of recurrent appendicitis, and 20 of these exploded into an abscess or general peritonitis before the third attack.

The operation during an interval seems a safer one than that during an acute attack, even if that is done early; for in the latter case you have no time to prepare your patient for an aseptic operation. The patient is in an extremely nervous condition, is fatigued from pain, his bowels are more or less distended, the site of the operation has been reddened or blistered by stimulating embrocations; so, as Cabot says, it is almost impossible to do an aseptic operation. And here I would reiterate Dr. Cabot's plea, that the general practitioner who has a case of appendicitis under his charge, should use antiseptic poultices, which will render an operation much safer if one has to be done in an emergency.

It is very much different in an interval between the attacks. You approach the patient under entirely different conditions; he has been prepared for the operation, both in body and in mind; his diet has been regulated; his bowels have been moved, and all flatus possible has been removed; and the field of operation has been made thoroughly aseptic.

The technique of the operation varies according to the individual taste of each operator. Dr. McBurney uses the cauter and ligature in all of his cases. Dr. Treves sews up all of his cases without drainage.

Dr. S. C. Gordon, in the *Boston Medical and Surgical Journal*, reports six cases with recovery. He believes that all cases can be carried through the acute

stage by means of salines and depletion, and that it is much safer to operate in an interval; he also sews up without drainage, even those in which he finds an abscess.

In conclusion, I would say that it does not seem to me possible to lay down any definite rules as to when the operation should be done, but that each case must be considered separately. It seems to me that if it were possible to carry a patient through the acute stage without operation it should be done, since the operation in the interval by a skillful surgeon carries with it such a small mortality, and the abdominal wound can be sewed up tight, therefore minimizing the danger of a subsequent hernia.

Clinical Department.

A CASE OF MALIGNANT ENDOCARDITIS.¹

BY WILLIAM E. FAY, M.D.

THE early recognition of malignant endocarditis is so often difficult to the clinician that I desire to read this case. It is with the hope that it may be suggestive of discussion which will elucidate the way of diagnosis.

The patient was an Irish waiting-maid of twenty-two. Of her family there is little knowledge. Measles in early childhood; joints swollen and painful, with rheumatic fever lasting one month at the age of twelve; catamenia beginning three years later, always regular; occasional headaches; and a futile operation to find a needle she thought lost in her foot, comprises the known previous history.

On June 22d last, she is reported as standing in a china-closet, during a thunder storm of unusual severity, attending to her duties. Suddenly she was unable to speak. She understood what was said to her. She knew the words she ought to say, but could not utter them. From her own statement she thought she was all right in every other way, because she could move her hands and feet, and see and hear and eat. She experienced a chill some time during the next two days, when she was placed in the Newport Hospital. In a few days more she began to be able to say a word or two. Sometimes she was unable to repeat a word just spoken. She gradually acquired increasing power of speech during the six weeks of her treatment there.

On August 5th she was transferred to the Carney Hospital, and admitted to the service of Dr. James J. Minot. She had partial aphasia and huskiness of voice. Pain in left side, under costal border. Temperature 102.5° F. in the evening, subnormal in morning. A trace of albumen with a few blood and vaginal epithelial cells found at this time soon disappeared. Urine otherwise unimportant. No error detected in reaction of pupils to light or accommodation, nor in the protrusion of tongue. No paralysis. Throat and lungs normal. Apex beat of heart seen in fifth interspace, inside the mammary line. Pulse full, regular, compressible. Systolic murmur quite loud at apex, propagated into axilla, heard posteriorly at border of left scapula, anteriorly lightly over præcordia to base. Pulmonic second sound increased. Splenic area considerably increased, but limits indefinite on account of extreme

tenderness at this time. No tenderness elsewhere. No extreme tympany. Skin sensations normal.

During the following two weeks her speech became pretty natural, except for a certain hesitancy. She had a daily rise of temperature in the afternoon with morning remissions between the extreme limits of 96.4° and 104.8°.

Ten grains of quinine given at height of fever, caused gradual diminution of temperature, tinnitus and headache. Eight grains daily in divided doses was not well borne. However, during administration of quinine the variance in limits of pyrexia was somewhat lessened. Examination for plasmodium malarie was negative in results.

The patient came under my observation, during the absence of Dr. Minot, in the second half of August. She presented an aspect of anxiety, pale, eyes becoming slightly sunken. Tongue clean. No cough. No dyspnoea. No hæmorrhages. No abdominal tenderness except over area of splenic dulness. This area extended from the sixth interspace to the costal limit, where during inspiration the edge could be dimly felt. Dull pain here was more or less constant. No rose spots or petechiae. Urine and dejections normal. Heart's murmur unchanged. Baffled in diagnosis, I asked Dr. J. J. Thomas to see the case with me and examine the blood. He found the red to the white as 100 to 1. Red normal. White in excess. Hæmoglobin 50 per cent. A condition more often pertaining to chronic, and after some acute diseases, as malaria and pneumonia, not typhoid fever.

About September 1st a small red spot appeared just below the trochanter of right femur, extending two or three centimetres. A small abscess developed at the centre, with infiltrated, uneven edge. Somewhat painful. Yielded a drop of pus. Healed in three weeks, under antiseptic dressings. Through this month patient gained a little strength. Splenic pain diminished. She sat up. A week more, and she was again in bed. Morning remissions of temperature are a degree or two less, and the evening rise higher. Pain recurs in the region of spleen. Urine becomes smoky; amount diminished; specific gravity 1.023; sugar absent; large trace of albumen; hyalin, fine, granular, fibrinous blood and epithelial casts; free blood and epithelial cells. It is five weeks since the urine was normal. In another fortnight there is one-eighth per cent. albumen; casts more numerous, of both large and small diameter. The spleen continues to be felt. Cedema of face appears. Semi-comatose condition supervenes.

On November 20th patient dies.

This illness extended over 122 days. In reviewing the time, it seems to divide itself somewhat into different periods. First aphasia is prominent, whether due to functional or organic cause? The kidneys showed no evidence to signify a causal relation to embolus. The mitral valve seemed responsible for a heart murmur, but this was thought to be an old chronic injury from an attack of rheumatism in childhood, and incidental to this illness. There had been no trauma. It was difficult to distinguish whether the trouble was motor aphasia or hysterical aphonia. There was no mind-blindness nor mind-deafness; and if Broca's region was impaired, lesion must have been extremely limited to be without some loss of function in the face, arm, or leg. In favor of the functional causation seemed to be the onset of the trouble coincident with her alarm from thunder and lightning, which frightened

¹ Read before the Boston Society for Medical Observation, December 4, 1893.

others about her; her age and sex. Also from the surgeon who sought the needle in her foot a year before, is learned her disposition then, which led him to suppose it might have been hysterically lost.

As this symptom passed, the question of malaria offers. There had been one chill reported. A suggestion of malaria accompanied her from the Newport Hospital. She had almost daily rises of temperature of four or five degrees, and an enlarged splenic area. But the lack of distinct periodicity, the tenderness disproportionate and extreme over a moderately enlarged spleen, the absence of plasmodium malarie in examinations made by the interne (Mr. Dewis), and the intolerance of moderate doses of quinine made this diagnosis improbable.

Typhoid fever was disregarded after observing that the peculiar temperature chart maintained its character constantly without any typhoidal curve, the tongue clean, no rose spots, and nothing abnormal with the bowels. In regard to tuberculosis, she had some hectic at times, progressive emaciation; and but for its rarity the skin lesion upon the thigh might have pointed to it, as it somewhat resembled the description in the books of such affections. Microscopic examination of scraping from same by Dr. Coggeshall discovered no tubercle bacillus. Examination of the choroids was not made. Tuberculosis of the spleen is always secondary, so far as I know. The lungs were repeatedly found quite normal, and no other origin of tubercular affection could be proved.

There was no condition of anemia shown by examination of the blood to account for the patient's condition.

Some splenic or peri-splenic abscess could not be excluded by the symptoms; but the infectious source to which it might be secondary, and the source of the sudden severe nephritis did not appear. Cultures from the blood were not attempted during life. Had they been successfully made, inoculations in small animals might have given certainty, where clinical signs left us in doubt until facts were obtained by autopsy.

Autopsy eighteen hours after death, by Dr. F. Coggeshall: Small stature, emaciation. Rigor mortis marked. Scar, size of silver quarter, under right trochanter. Whole brain very soft. Left temporal lobe and adjacent portions especially softened and yellowish in color.

Organs were taken to Dr. W. F. Whitney, at the Harvard Medical School, who found the following: Heart of normal size. Right side normal. Left auricle slightly dilated. In it and on surface covered with small papillary fibrous projections which were also found on the edge of the mitral valve. With these were also associated soft, grayish, opaque small masses, especially abundant on the chordae tendinae. Left ventricle presented nothing abnormal, nor was anything abnormal noticed in the wall of the heart. Lungs, liver and stomach presented no marked deviations from normal. Beneath the mucous membrane in the lower part of the ilium were numerous small hemorrhagic spots. At the root of the mesentery was a swelling, the size of an egg, composed of clotted blood, which seemed to be more or less extravasated into the tissues. The spleen was twice its normal size. Surface marked by several depressed cicatricial places, the base of which had a yellowish aspect. On section showed the pulp markedly increased; the cicatrized portions above mentioned corresponded to more or less wedge-shaped, yellow, opaque extensions into the sub-

stance of the spleen, and which were sharply differentiated from it. The kidneys were large, capsules slightly adherent. On section, found to be swollen, very moist surface, Malpighian bodies appearing as minute whitish bodies in the midst of grayish cortical substance, and with numerous small hemorrhagic spots. There were several cicatricial places in the kidney similar in character to those in the spleen, and which in like manner were continued into yellowish, sharply differentiated, somewhat wedge-shaped nodules. Anatomical diagnosis: Softening of the brain; chronic verrucous endocarditis, associated with acute vegetative endocarditis; anæmic necrosis of spleen and kidneys, results of infarction; acute diffuse and glomerulo nephritis.

I am especially indebted to Drs. Minot and Temple for permitting me to report a case from their services at the Carney Hospital, and to Dr. Whitney for his examination of the organs.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, December 11, 1893, the President, DR. C. F. FOLSOM, in the chair.

DR. J. J. PUTNAM made an oral communication concerning

A CASE OF MYXEDEMA.

The patient, who was present, was a woman of forty-four, and of Irish parentage, though she had lived a great many years in America. It is interesting to note that her sister, who still lives in Ireland, also presents symptoms which strongly suggest myxœdema.

The patient's symptoms were of gradual onset, and date back perhaps a year. Previously to this she had been in good health, except that for four years past the menstruation had been irregular, and for two years she had had "hot flushes." A puffiness of the hands was noticed a year ago, but not much was thought of it until six months ago, when a swelling of the face and a slowness and huskiness of speech attracted her attention more forcibly. At this time, also, her eyelids began to droop, so that she had to drag them up by wrinkling the forehead. Soon afterwards the feet became swollen, and the hands were noticed to be dry and scaly.

These changes are said to have been gradually increasing, but even now there is nothing to attract the notice of a casual observer.

On close examination there is observed, besides the above-mentioned conditions, a slowness of the motions of the tongue, a marked trace of the characteristic alabaster appearance of the eyelids, a slightly subnormal temperature (98° F.), slow pulse (69), and typical "supraclavicular fullness." The hair has been falling of late. The urine is normal. The diagnosis was confirmed by the fact that under treatment by feeding with desiccated sheep's thyroids (five to ten grains daily), which had been going on for two weeks, there had been a steady gain in all respects, except that the hair had continued to fall out.

[At the present time of writing this improvement

progressed still further, to the patient's great con-
The temperature and pulse are now normal; weight, which was 187, has fallen a number of lbs; the appearance and manner suggest greater
ness. An examination of dried and stained specimens of blood, made by Dr. Richard Cabot, shows the normal proportion of whites and reds, and no unusual liabilities.]

R. F. C. SHATTUCK presented

REPORT OF FOUR CASES OF MYXŒDEMA TREATED
BY THYROID EXTRACT.¹

DR. J. J. PUTNAM: I have been much interested in this subject for the last year or more, and have been very glad to hear Dr. Shattuck's paper. To speak of points to which he has alluded, I should like to say a word about the matter of dosage. I have recently read of a case where, from taking a single rather large dose of sheep-gland, the anginoid symptoms to which he has referred came on, and were quite serious. It is a curious thing that not only cases of this character, but also pains of other kinds, have shown themselves from time to time—I think especially intercostal neuralgia. Also, in one of Mache's cases, great prostration occurred, with some bowel complication, requiring the patient to keep the bed for some time.

With regard to the frequency with which this trouble occurs, it seems to me beyond question that some of these cases are often diagnosticated as Bright's disease. The second case that I saw, and in the treatment of which I took part, had a cousin and an aunt, both of whom had died long before anything was known of myxœdema, but who had certainly had the disease in a pronounced form. I knew them well, and one of them was believed to be a typical case of Bright's disease. The face was swelled, the lips were thick, and the voice was husky and hoarse. The face presented the same appearance, though in more marked degree, with that shown in the colored illustrations that Dr. Shattuck passed around. The sister of the patient whom I showed this evening also, from her account, would seem to be a victim of the same disease, although not recognized. I have not seen her; but she is said to have shown a similar loss of hair and marked weakness (without pain and without the signs of any particular disease), and puffiness of the face and hands. My second patient, who is still under the care of my brother, was at one time also supposed to have Bright's disease, because she had had albumen and casts in the urine for some time. Those have now disappeared with the treatment. I think it probably true, as Dr. Shattuck says, that the dose of thyroid extract to overcome symptoms will have to be increased in cold weather, because my first patient, who improved to a considerable degree between July and October, with the advent of cold weather fell off considerably, and the œdema of the eyelids returned to a marked degree. With regard to the first case that Dr. Shattuck described, and which I am extremely glad to have had the chance of seeing through his kindness, although I am not inclined to insist that his diagnosis was not correct, and although I have no doubt that it belongs in general to a large class of trophic disorders of peculiar kind, still it did not seem to me to be a typical case of myxœdema. The speech, instead of being slow, was quick; the mental

condition was active, instead of being very dull and apathetic; and the temperature was not subnormal, as has been the case in almost all the cases reported. Dr. Dercum described two years ago two cases which it seems to me should be mentioned in this connection. They were cases characterized by a peculiar form of obesity, with neuralgic pains and a few symptoms suggesting myxœdema, although many symptoms were wanting which would be necessary to make a complete picture of the disease. It is an interesting question, which has come up in connection with recent researches of Vermehren, of Copenhagen, whether some of the affections from which old people suffer, such as weak action of the heart and nutritive disorders of various kinds, may not be due to a slight failure of the thyroid. At any rate, he found that giving thyroid improved their condition. Thyroid has been used successfully against certain forms of obesity; and I have had several cases where patients not having myxœdema have lost weight for a time very rapidly, two or three of them losing in the neighborhood of forty pounds. The loss did not, however, continue indefinitely; and there are also other troubles in which it would appear we may possibly be able to use it with advantage.

DR. E. D. SPEAR: I want to add one suggestion in regard to the function of the thyroid gland, and that is the probable regulation of the cerebral circulation by means of the thyroid through the sympathetic system. I find that in certain aural cases where there is a certain noise in the ear which may be called a bruit, the thyroid gland is always enlarged; that is, the lobes of the thyroid are always enlarged, and that in those cases the pulse is always raised usually to 120 or 130 beats a minute. I only want to speak now of what has been referred to as pain about the heart in those cases where the thyroid extract has been given. I do not know as there is any connection, but I do know that the thyroid in some obscure way controls the cerebral circulation through the sympathetic; how it does it I cannot say. These clinical observations which I make in these cases are of interest, and, I think, should be studied in connection with all those obscure affections in which the thyroid is spoken of. It is a fact that, if in these cases I press upon the thyroid gland with my thumb to make massage to a light extent, the pulse drops immediately after from 120 to 60. If I continue the pressure the patient faints. If I stimulate the thyroid gland where it is enlarged by external irritants, I shall, instead of depressing the circulation, stimulate the pneumogastric apparently, and tone up the heart so that the pulse is made normal. These noises in the head are described by the patient as roaring noises, and are always accompanied with changes in the power of hearing, but with no obvious changes in the ear. I always found, however, that the turbinate body was enlarged, and that treatment in early cases—that is, in cases lasting from six weeks to six months, we will say—the simple application of heat to the thyroid gland by means of hot water upon a towel or flannel is sufficient to stop the noise and improve the hearing. Of course, in all, or most all my cases, I make local treatment. In the few cases which are slight I rely upon heat; but were I to map out a full treatment for a case of this kind where there is noise in the ear, deafness, I should, in addition to the heat to the thyroid, give a nerve stimulant; that is, strychnia in full doses, and apply mus-

¹ See page 177 of the Journal.

tard or some counter-irritant to the heart, and make local applications to the ear through the nose.

One other thing that I would like some of the neurologists to take up is to prove if my observation is correct. Of course, I know I am correct in regard to the function of the thyroid as regulating the cerebral circulation, but whether I am correct in this I am uncertain. In a large number of cases it is possible to induce sleep by means of application to the thyroid. I can relate one experience which will prove it was possible in one case to induce sleep by hot applications. One of my patients used to awake at all hours of the night. She was the wife of a fireman who was deaf, and she listened for his tapper. At any time of night or day she roused him and got him ready for the engine. After she came under treatment for nasal obstruction, I put her upon applications of heat to the thyroid. One afternoon at three she felt uncomfortable, had some disturbance in the head, made an application to her thyroid, and went to sleep! There were two alarms of fire, and at the end of an hour a policeman went in and asked what was the matter that she did not wake him up. I should like to have neurologists try this experiment, which is simple, but a very powerful remedy in cases of insomnia. The danger to be avoided is the depression of the heart if the applications are continued longer than ten or fifteen minutes at the outside.

DR. F. C. SHATTUCK: I quite agree with Dr. Putnam that my first case was not a typical one of myxœdema. Had it been typical I should not have sent it to him for an opinion. The absence of mental sluggishness and of subnormal temperature does not weigh much in my mind. Increasing experience is constantly showing us deviation from the symptoms as now laid down in the books. The Chairman saw this case; and I should be glad to have him give his opinion of it.

DR. FOLSOM: I have not consulted my notes; but I am quite sure that this is the fourth or fifth case which I have seen. The others were before anything was known about the thyroid-extract treatment. It seemed to me an unquestioned case of myxœdema. It is quite true that there was no mental torpor, in the strict sense of the word, to be observed; but I am inclined to think there was, in fact, because there was a certain amount of mental momentum, so to speak, got up by the exhilaration of the patient sufficient to mask a considerable degree of mental impairment. As it seemed to me, the essential points were such that I felt quite confident of the diagnosis of myxœdema.

DR. M. H. RICHARDSON showed a specimen of

AN APPENDIX OBLITERATED IN THE GREATER PART OF ITS LENGTH.

This specimen I removed this morning from a man thirty-eight years of age. The history of the case is very interesting in connection with the condition found at the operation. He had been subject for four years to occasional attacks of violent pain in the epigastrium. From the epigastrium the pain would go into the right iliac fossa. On Tuesday, February 7, 1893, he had an attack of "terrible pain" in the epigastrium, with vomiting. The fever lasted for several days. He supposed he had the colic, and treated himself for it. At the end of five days he sent for Dr. Marshall, of Lynn. He went on from bad to worse until Sunday, the 19th, when I saw him. The whole of the lower part of the abdomen from right to left was filled by a

large, fluctuating tumor. It pressed also upon the rectum. I opened, by an incision parallel to Poupert's ligament, without infecting the general abdominal cavity. The mass was made up of several abscess-cavities. The appendix could be felt, very large and thick, intimately adherent to the surrounding parts, so that it seemed to me inadvisable to make any prolonged efforts to separate it. One large tube was put down into the pelvis, and another toward the bladder. About the tubes sterile gauze was packed. The temperature went down after the operation, but about two weeks later there was a discharge of a pint of pus. After this he made a good convalescence.

On November 21, 1893, I examined him again. Since the operation he had been perfectly well till three weeks ago, when he had another spell that came on in the same way as the others had—with pain in the stomach. There was a little fever with this attack. Examination of the scar showed a well-marked ventral hernia, slight in extent, but unmistakable. There was no tenderness or pain. In view of the second attack, in its onset precisely like the first, and considering the hernia in the scar, I advised him to have an operation performed, first, for the radical cure of the hernia, and secondly, for the removal of the appendix, should it seem desirable after exploration. I cut out the scar tissue this morning, and came down upon the cæcum. There was no trace of the formerly extensive abscess, except a little induration behind the cæcum. The appendix was attached to the posterior and outer cecal wall by strong adhesions. These had to be cut before the appendix could be separated. There was nothing left of this organ except a small stump and a rounded extremity. Between the two, as the specimen shows, there was nothing but a fibrous cord, which may have been nothing but the remains of the inflammatory process. The condition of the appendix, in my opinion, would not have justified an operation for its removal, had we known it beforehand. The one attack of which he complained did not seem to me alone sufficient to justify this operation. The presence of the hernia was a real menace to his health, and alone justified the interference. Having opened the abdominal cavity, the removal of the fragments of the appendix seemed to me a rational procedure, especially as enough of the stump was left to account for the symptoms of the second attack.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, Monday, December 4, 1893, DR. J. B. AYER in the chair.

DR. W. E. FAY described

A CASE OF MALIGNANT ENDOCARDITIS.¹

DR. AYER: I should like to ask whether at any time the temperature rose more than once in the twenty-four hours and also whether it is not a very frequent symptom to have an irregular rise twice in the twenty-four hours?

DR. FAY: There was an absolutely constant afternoon rise, except when modified by quinine; one rise during the day, never two. I do not know how frequent it is to have the temperature rise twice in the twenty-four hours. In the *British Medical Journal* a

¹ See page 189 of the Journal.

year ago last March, in a paper by Dr. Frederick Taylor, is pointed out the long duration of the pyrexia which was seen in some cases, during which the fever was almost absolutely regular.

I should like to mention one case of endocarditis I came across among a number of cases from various sources of infection. The duration of the case was, within two days, the same as this one, and it passed through all the stages and was recognized in life.³

Two months after the illness began a rabbit was inoculated with a culture of a staphylococcus made from a drop of blood taken from the finger of the patient. In another month the rabbit died. There was an endocarditis of remarkable intensity, vegetations arising from the valves, and bloody effusion into the peritoneum. In nearly another month the patient died. Autopsy showed precisely similar conditions.

DR. M. H. RICHARDSON showed a specimen of

FIBROMA OF BREAST, WITH LARGE CYST SIMULATING CARCINOMA.

This specimen was removed two days ago from a woman of fifty-three. It was my intention to show this tumor in connection with a similar one removed from a woman of thirty-one. Both involved totally the left breast and both contained a hard mass distinct from the main swelling. The axillary glands were enlarged enough to be felt distinctly in each case. I advised operation in each. This specimen from the woman of fifty-three proves to be benign—diffused, intracanalicular fibroma—without a suspicion of malignancy; while the breast from the young woman contained a nodule of cancer three centimetres in diameter and was itself a mass of fibrous tissue formation.

Dr. W. F. Whitney's report is as follows:

"Mrs. B., age fifty-three. On section it was in general, firm and fibrous looking, and the surface was interspersed with numerous cysts of size varying from a pin's head to one of the size of a small egg; the lining of this was smooth and the contents thin and watery. Microscopic examination showed dilated ducts and acini of the gland lying in a matrix of dense fibrous tissue. Some of the dilated spaces were more or less sinuous, and suggested a growth into the lumen of a canal of fibrous tissue. The diagnosis is a chronic, diffuse, fibrous-tissue formation in the breast, with retention cysts. The whole of the gland was affected."

"Miss P., age thirty-one. The tumor of the breast and axilla from Miss P. showed a large, densely-fibrous growth occupying the greater part of the breast. At one part it was opaque, more homogeneous and grayish. Microscopic examination showed remnants of gland acini, surrounded by dense layers of fibrous tissue, with quite hyaline-looking walls. Involving these were irregularly-branching lines of solid epithelial cells. The axillary glands were enlarged, and contained large epithelial cells separated by a little fibrous-tissue stroma. The case is one of a cancer (rather of the medullary type) which has invaded a breast where had previously existed a chronic diffuse fibrous-tissue formation."

The interesting clinical question was that of diagnosis. In the younger patient there seemed a strong doubt as to the presence of cancer, though the enlarged axillary glands—much more pronounced than in the older woman—pointed more to a malignant tumor than the slightly enlarged ones in the older patient.

³ Referred to in *Sajous's Annual* for 1891.

I advised operation in the latter case because I believe that all mammary growths in women over forty should be explored most thoroughly; and in the former because, though in a young woman, the appearances were very suspicious. Cancer developing in a diffuse fibroma is very unusual in my experience; its occurrence in so young a woman emphasized the importance of removing such tumors early. Not that the danger of malignant degeneration is pressing; but unless we are able positively to exclude malignancy, we ought to remove, or at least, to explore, all suspicious tumors, even if they cause only discomfort and anxiety.

I have frequently found the axillary glands enlarged in benign tumors, where there is no reason for their presence beyond a possible irritation. This enlargement, if not one of irritation, is usually coincident with a swelling of the glands of the opposite axilla.

The slowness of growth was another point in favor of the benignancy of the cystic tumor. The cysts themselves are often so tense that it is impossible to tell whether they are the solid irregularities of cancer or not. Even after the removal of this specimen, it was impossible to exclude malignant growths until the tumor had been all cut to pieces and several questionable points had been examined microscopically. The mistakes likely to occur if the diagnosis rests upon sections made with a punch before operation are obvious. In the young woman's case the specimen removed by the punch very likely would have contained none of the malignant structures, and depending upon an apparently scientific demonstration of security, I should have allowed the patient to lose the favorable moment for operation. Not that the exploring punch is of no use. On the contrary, if it does catch the malignant neoplasm it is a demonstration that may be looked upon as final; if it does not, we must at times still make the radical incision.

In these operations now I close the wound without drainage. My experience in this procedure shows the rapidity with which a man's ideas may change. I do not feel ashamed to say that my views on many subjects are very different from what they were a year ago. I dare say that in a short time hence I may do these operations in a very different way from what I do them now, but it seems at the present time as if there were not much improvement to be made in the technique of operations of this sort. The mortality in breast-operations in my experience has gone down from four or five per cent., in the carbolic-acid times to practically no mortality in the last four years. We have also got rid of the disagreeable features of drainage by means of careful asepsis and absolute hæmorrhage. If we are careful not to operate in hopeless local disease or when there is hopeless disease of the internal viscera, the mortality must always remain very low indeed.

One thing I forget to say about the desirability of operating in cases of fibromata in young women in whom the question of disfigurement is important. Were it not for the cases in which Dr. Whitney has found malignant disease complicating these benign growths, I should not insist upon their removal except in the rarest instances. When the tumor is small and movable, I should not interfere. When the tumor does not demand the removal of the whole breast, the disfiguring scar can be avoided by Gaillard's method of post-mammary dissection.

DR. VICKERY: There is a kind of hard, painful

lump that quite young women have in their breasts. It is a source of great anxiety. When I was a student such lumps used to be left in; now a good many surgeons take them out. I should like to ask Dr. Richardson if he will tell us his view about the matter.

DR. RICHARDSON: My advice to a young woman with a fibroma of the breast is this: if it troubles her very much, she can easily and safely have it removed. In leaving it alone the dangers to health are very slight. The pain and tenderness are frequently the result of her constantly examining it; if she lets it alone, and if it is not very large, the tumor often disappears. They are sometimes very large. I have seen them occupying the whole breast, weighing perhaps a pound, though the ordinary fibroma is seldom beyond the size of a hen's egg. A tumor that causes discomfort ought to be removed because it can be done with great ease and safety. In none of these cases is excision necessary on account of the danger to life if you can be sure that no malignant complication exists.

Recent Literature.

Introduction to the Catalogue of the Collection of Calculi of the Bladder. By SIR HENRY THOMPSON, F.R.C.S., etc. London: J. & A. Churchill. 1893.

This little volume is nothing less than a summary of the entire experience of its eminent author with reference to operations for stone and foreign bodies in the bladder. It accompanies the more extensive catalogue which, prepared and revised with great care, was presented by Sir Henry, together with the cabinet containing his collection of calculi and foreign bodies removed from the bladder by him, to the Hunterian Museum of the Royal College of Surgeons in 1892. This collection represents the whole of Sir Henry's work in this department of surgery, from his first case in 1857, up to the date of presentation, which, with the additions made between that time and April, 1893, comprises 1,013 operations.

The "Introduction" furnishes statistical tables of the results of these operations and of the more important points connected with them, as well as comments by the author concerning the matters of especial importance in regard to the subject. We are glad to note, under the heading "Lithotripsy," that Sir Henry gives as his latest expression in the matter the full credit which is its due to the notable achievement of Dr. Henry J. Bigelow ("Litholapaxy").

Sir Henry's "Introduction," etc., is a *multum in parvo* which will well repay careful study, since it gives, even in this condensed form, a valuable record of part of the work of one of the most remarkable and talented of surgeons and men of our day.

A Practical Treatise on Materia Medica and Therapeutics. By ROBERTS BARTHOLOW, M.A., M.D., LL.D., Professor of Materia Medica, General Therapeutics and Hygiene in Jefferson Medical College, Philadelphia, etc. Eighth edition, revised and enlarged. New York: D. Appleton & Co. 1893.

The recent revision of the United States Pharmacopœia has led Professor Bartholow to bring out a new edition of this well-known and deservedly popular work: and we need only say that in it, he has adopted the metric system and included such of the newer remedies as he deems worthy of recognition.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 22, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DISEASES DUE TO "HARD TIMES."

It would doubtless be an interesting study to investigate from the inductive side the morbidity in communities directly traceable to business depression; this, however, would require wide observation and careful collection and collation of data, and the subject would be at the best a very complex one.

The most that we can attempt to do on the present occasion is to approach the subject from the deductive side; given the want and distress into which large portions of communities are plunged from lack of work and lack of money, to deduce the necessary pathological consequences in accordance with well-known laws.

Seasons like that through which this country has been passing are times of great psychical depression. There is (or has been) profound discouragement among employers and employed; among men of business making no money (or losing), and workingmen idle, with distress and poverty before them. With multitudes there is paralysis of the higher incentives and emotional forces, and psychical failure and degradation.

Among the many startling things uttered by Senator Stewart, in his lengthy speeches before the Senate of the United States recently, was the statement that the mental stagnation, degeneration and darkness of the Middle Ages was principally due to diminished production of the precious metals and consequent depression of business and lack of remunerative employment for the masses.

Times of financial depression like the present are fraught with anxiety and worry among all classes of society; and anxiety and worry, along with want of nourishment and hereditary predisposition, are powerful factors in the production of insanity. "Low wages," says Maudsley, "mean poverty and bad nourishment, and lunacy shows a distinct tendency to go hand-in-hand with pauperism."

The statistics of our insane hospitals bear out this statement; nor can we be surprised at the large access-

sions to the ranks of the insane from the lower classes during the past year. When chronic worry coincides with chronic want of work, some form of mental degradation is almost sure to supervene, for "mental exercise is the true foundation of mental health."

If we may trust Huchard,¹ mental emotions (and he specifies chagrin, anxiety, disappointment, worry) may have a real and positive influence in the origin and development of *cardiopathies*, and, in particular, of *arterio-sclerosis*. The order of morbid events, according to this writer, is as follows: Spasm of the arterioles (due to the emotion), hypertension of the arterioles and capillaries, sclerosis of the arteries, sclerosis of the viscera. The existence of arterial spasm under the influence of even trifling emotion has been demonstrated by the experiments of Mosso by the aid of his plethysmographs. "If now," says Huchard, "you have a state of prolonged or chronic emotion, as where the person is in a protracted worry, or is profoundly, permanently disheartened by losses and adversity, you have a condition of almost permanent vascular spasm and of arterial hypertension."

We have not space here to give Huchard's explanation as to how this affects the vasa-vasorum and the nutrition of the arteries. He finds reason for the belief that strong and repeated emotion may determine cardiac affections by its incessant action on the peripheral circulatory system; "and this," he adds, "is one of the reasons why arterio-sclerosis is (according to my observations) so frequent in the medical profession, pre-eminently the kind of life entailing overwork and worry."

Doubtless, if this writer's views are correct, the past year, by its chagrins, anxieties and cares, must have been a very eventful year in the pathogenesis of arterio-sclerosis.

It hardly needs to be said that inebriety is a disease no less prevalent in hard times than in times of prosperity. Idle men naturally flock to the saloons, and evil and misery drive the poor and the desperate to seek solace and forgetfulness in strong drink.

Among the diseases to which times of great business depression have a causal relation are all those derangements of the alimentary canal and of nutrition which are the result of insufficiency or improper quality of the ingesta. That human beings this present winter in all our cities are without sufficient food is painfully known to physicians and all others who are brought into daily contact with the poor. In very many instances the physician feels that food and not medicine is needed. Many families, too proud to receive charity, are living on a starvation diet. They cannot afford meat, and they buy only the poorest, cheapest foods. Hence the evils attendant on anæmia and inanition are soon apparent. The poorly fed soon fall a prey to grave diseases (tuberculosis, pneumonia, typhoid fever, even influenza, etc.) because their vital resistance is weakened. Children brought up on a meagre diet become frail, sickly and neurotic. Are

we destined to witness, as the outcome of this long period of business depression, a generation of miserable candidates for tuberculosis, for hysteria — physically stunted, intellectually undeveloped, unfit to bear the burdens of life, a burden on society.

To the ills which we have mentioned, we might add all the pathological results of insufficient fuel and insufficient clothing.

Doubtless with the starting up of idle machinery all over the country, there is the promise of future prosperity; and the greatest boon which we can ask for the idle and unemployed is the hygiene of regular work, for this means plenty of food, enough clothing, strength of body and mental health.

THE SUPERVISION OF THE INSANE IN NEW YORK.

THE leading medical journals in New York continue to express thorough dissatisfaction with the State Commission in Lunacy, for the reasons which we have suggested in a previous number of the JOURNAL.¹ In a recent editorial in the *New York Medical Journal*, the statement is made that on all sides in the State the tendency of the Commission in Lunacy to evolve itself into an enormous political machine has been subjected to severe criticism from honorable men of every profession, and that the voice of reproof grows louder every day as the lowering ambitions of the commissioners become clearer and clearer.

A bill has been proposed in the Assembly to abolish the Commission in Lunacy, and to confer upon a committee of the State Board of Charities — really upon the secretary of such a committee — the work of supervising the care of the insane in the State institutions. This plan is essentially the same as those which have proved so satisfactory in Massachusetts and Pennsylvania; and the reputation of the New York State Board of Charities for excellent work is such that it will be quite safe to place additional responsibility in its hands.

Moreover, the Board has already distinguished itself for investigations and recommendations with regard to providing for the insane, and has a familiarity with the subject that must prove of great practical use, if it can be made available. In continuation of the studies of the Board, Dr. Stephen Smith, formerly State Commissioner in Lunacy, has formulated a number of suggestions² for improving the administration of insane asylums and for increasing the comfort and chances of recovery of the insane, in which he has especially recommended the principles embodied in the proposed law.

We have in this State been so fortunate in keeping politics out of our public institutions and in having the management of our State Charities in the hands of public-spirited persons devoted to their work, that it is difficult to appreciate how important is the issue at

¹ Huchard: *Maladies du Cœur et des Vaisseaux*, Paris, 1890.

² Vol. cxxix, p. 608.

³ *American Journal of Insanity*, January, 1894, pp. 325-344.

stake in New York. The proposed change in the law is in the right direction; and we hope that it may be soon brought about.

MEDICAL NOTES.

A NATIONAL BUREAU OF HEALTH. — We learn that the bill presented to Congress by a committee of the New York Academy of Medicine, for the establishment of a Bureau of Health, has been so essentially modified that the new draft is much more likely to represent the views of the various health bodies of the country, and, in consequence, to have favorable action at the hands of the authorities at Washington.

YELLOW FEVER AT RIO JANEIRO. — The yellow fever epidemic at Rio Janeiro has started up again, and is increasing to a considerable degree, there being an average of about forty new cases each day. One case has occurred on the United States cruiser *Newark*, and the vessel has been ordered to Montevideo to be disinfected.

SUCCESSOR TO PROFESSOR MOLESCHOTT. — Professor Luigi Luciani, of Florence, has been appointed to the Chair of Physiology in the University of Rome, to succeed Professor Moleschott.

THE STUDY OF LEPROSY IN ICELAND. — The Danish Parliament has voted the sum of \$840 for the expenses of a medical mission to Iceland for the purpose of studying the extent to which leprosy still prevails on that island. The mission, which is to consist of Drs. Ehlers and J. Ulrich, of Copenhagen, with an Icelandic physician as interpreter, will make its investigation in July and August of the present year.

AWARD OF THE RIBERI PRIZE. — The Riberi Prize, founded by Prof. Alessandro Riberi, has just been awarded to Dr. Camillo Golgi, Rector of the University of Pavia, and Professor of General Pathology, for his essay upon Malarial Fever. The prize amounts to \$4,000, and is open to international competition every five years. The subject must be one of purely medical interest, and the essay be the result of original research. There were three essays this year deemed worthy of final consideration, that by Dr. Golgi being finally awarded the prize. The others were by a Frenchman and a German.

MEDICAL PRACTITIONERS IN SCOTLAND. — The last volume of the census of Scotland, for the year 1891, gives a list of 7,709 medical practitioners, or one to every 522 inhabitants. This proportion seems rather large until it is noted that the list of medical practitioners includes physicians, surgeons, dentists, veterinary surgeons, sick-nurses, midwives and invalid attendants. An analysis shows that there are but 2,595 physicians and surgeons, or one to every 1,550 inhabitants. There were only twelve women physicians.

CORONERS OR MEDICAL EXAMINERS? — The clumsiness and inefficiency of the old coroner system is be-

coming each year more widely appreciated. The committee appointed by the Medico-Chirurgical Society of Montreal to suggest modifications in the present law relating to coroners' inquests has recommended that the office of coroner be made a purely judicial one; and (1) that salaried medical examiners be appointed to investigate all deaths occurring under circumstances calling for medico-legal investigation under any act, and that these officers be given authority to make such medical examination of the body as may be necessary to determine whether death was due to violence or not; (2) that in every case the medical examiners report the result of their examination to the coroner or other judicial officer charged with investigating the legal side of such cases, who, in case of violent death, shall make such investigations and take such measures as are necessary for the proper administration of the law.

HENOCH'S SUCCESSOR. — Prof. Johann Otto Leonhard Heubner, of Leipsic, has finally accepted the chair of Children's Diseases at Berlin made vacant by Henoch's retirement. At first he declined the position, owing to its being only an Extraordinary Professorship, while his own position at Leipsic was that of Ordinary Professor. Heubner, who is fifty-one years old, has done practically all his work in Leipsic. He was assistant to Wunderlich in 1868 and private docent in 1869.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the six days ending at noon, February 20, 1894, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 26, scarlet fever 23, typhoid fever 2, small-pox 7. There was one death from small-pox. The small-pox cases were reported at about the same time from three different parts of the city. There was some difficulty in accounting for one of the cases, that from the South End, until the arrival at the hospital of another patient from the West End who had acquired the disease from visiting the family in South Boston who were supposed to be ill with chicken-pox. The South End patient was delighted to see in the West End patient a friend whom he had visited some days before, and the chain of evidence was complete.

SMALL-POX IN MASSACHUSETTS. — During the past six days there have been reported to the State Board of Health six cases of small-pox from places outside of Boston. One case in Worcester and five cases in Holyoke.

A BEQUEST TO THE HARVARD MEDICAL SCHOOL. — The will of Rev. William C. Moseley, of Newburyport, bequeaths \$50,000 to Harvard College, to endow a professorship in the Medical School. Other bequests in the will were \$20,000 to the Massachusetts General Hospital, for beds in memory of his son; \$10,000 to the Boston Lying-in Hospital; \$10,000 as a trust to the Perkins Institute for the Blind; and \$10,000 to the Anna Jacques Hospital, of Newburyport.

NO MEDICAL STUDENTS TO BE ALLOWED IN THE CHARITY CLUB HOSPITAL.—The Women's Charity Club, of Boston, has voted, 43 to 38, forbidding all medical students the privileges of clinical instruction at operations performed in the hospital of the club. This is the final decision of the club on the question, which has been before it for some time, whether small numbers of last-year or graduate students might not be allowed to witness gynecological operations. The privilege was asked especially for students of Tufts Medical School, but no distinction has been made, and all are to be excluded.

THE FEET OF CAMBRIDGE SCHOOL-CHILDREN.—An order was passed last week in the Cambridge School Committee authorizing Dr. G. W. Fitz to make examination in the Peabody School of that city, of the rapidity and touch of pupils, and to take measurements of their feet. The latter statistics are to be taken in reference to the development of the arch of the foot.

VIVISECTION IN THE PUBLIC SCHOOLS.—The Committee on Education, of the Massachusetts Legislature, gave a hearing last week on the proposed bill to prohibit dissection or vivisection in the public schools. The bill was favored by representatives of the Society for the Prevention of Cruelty to Animals on the grounds, that vivisection is cruel and unnecessary, and because it teaches children to practise cruel acts, and is calculated to cause suffering to animals, and does no good.

COMMITTEE ON PUBLIC HEALTH HEARINGS.—The Committee on Public Health, of the Massachusetts Legislature, gave a hearing on Monday, February 19th, upon a proposed bill for the establishment of hospitals or wards in the various cities of the Commonwealth for the treatment of venereal disease. The hearing of the same committee upon a proposed bill for the construction and maintaining of hospitals for contagious diseases in the various cities and towns, said hospitals to be under the control of the local boards of health, which was ordered for the same day, was postponed to March 9th. The hearing on public vaccination was postponed to March 5th.

Miscellany.

PRESIDENT ELIOT ON THE REGULATION OF ATHLETIC SPORTS.

In the annual report of Harvard College for 1892-93, just issued, President Eliot devotes considerable space to a consideration of College Athletics. According to our custom, we shall notice this report at length. This week we can only give the conclusions reached by the President in regard to the regulations of College Athletics. Under the head of "Possible Checks on Excess in Sports," he says:

"If the evils of athletic sports are mainly those of exaggeration and excess, it ought not to be impossible to point out and apply appropriate checks. The fol-

lowing changes would certainly diminish the existing evils: (1) There should be no Freshman intercollegiate matches or races; (2) no games, intercollegiate or other, should be played on any but college fields, belonging to one of the competitors, in college towns; (3) no professional student should take part in any intercollegiate contests; (4) no student should be a member of a university team or crew in more than one sport within the same year; (5) no foot-ball should be played until the rules are so amended as to diminish the number and the violence of the collisions between the players, and to provide for the enforcement of the rules; (6) intercollegiate contests in any one sport should not take place oftener than every other year. Finally, if trial shall prove the insufficiency of all these limitations, intercollegiate contests ought to be abolished altogether.

"These suggestions are by no means of equal importance; some of them concern many persons, and some but few; but all or any of them could be put into force by a single college without diminishing that college's chances of success in such intercollegiate contests as it undertook.

"Different persons will undoubtedly strike the balance differently between the advantages and disadvantages of athletic sports; but one important fact will for many people incline the balance in favor of the sports—the fact, namely, that there has been a decided improvement in the average health and strength of Harvard students during the past twenty-five years. The gain is visible in all sorts of students—among those who devote themselves to study, as well as among those who give much time to sports. In 1888 the Faculty passed a useful vote to the effect that all holders of scholarships were expected to present themselves twice every year to the Director of the Gymnasium for a physical examination. The Faculty passed this vote under the impression that the bodily condition of these hard students would be found to be unsatisfactory; but it has turned out that, though some were weak, others were strong, and that the development and condition of the larger number were fairly good."

THE PATHOLOGY OF BICYCLING.

THE list of diseases of occupation has received an addition, this time a whole pathology; and the bicycle is to blame. The fear of kyphosis has terrified the young man into an erect position upon his wheel; but now a French physician brings forth an array of lesions caused by riding the velocipede which is suggestive of the extent of the present passion of Parisians for the wheel.

Dr. Pezzer¹ reports a considerable series of cases where more or less injury has been caused by the pressure of the saddle upon the soft or bony parts of the rider. Superficial lesions he has seen almost entirely on female riders; they consist of inflammatory affections of the labia majora, the urethra and adjacent parts. Twice he observed acute lesions of the hæmorrhoidal veins, with tumor and hæmorrhage in men; twice, also, acute retention of urine from prostatic irritation. Many patients were troubled by prolonged erections while riding, due to impeded venous return. There were several cases of annoying anæsthesia of

¹ Annales des Maladies des Organes Génito-Urinaires, January, 1894.

the regions supplied by the pudic nerves. The more serious lesions, however, occurred in the urethra; caused in women by friction, and in men by prolonged pressure on the bulbous portion. One patient suffered from ystitis after riding; and there were several cases of ruptured urethra (periurethral abscess), and one case of acute dislocation of the kidney.

It will be seen that after all bicycling is but little less dangerous than foot-ball.

THE PRESENT GENERATION.

AN overtaxed nervous organization is not the peculiar possession of the American people of to-day, as has been claimed. In his opening lecture on Therapeutics Landouzy gave the following picture of "the present generation of neurotics, which numbers so many youths of enfeebled ardor, of waning desires, of sterile intellects, and of saddened, restless and suspecting character; so many young women who are always anxious, dissatisfied and of constant functional instability, never ill but always disordered; so many impatient, capricious women, at once charming and unendurable, of strange *états d'âme*, ruled by casuistry, full of sparkling laughter and of ready tears, with high-pitched voice (exhausting but inexhaustible) whose talk is inconsequential, discursive and hyperbolic; so many women who are despondent, never satisfied, in love with realism not with the ideal, who will soon have eyes only for the impressionists, taste only for symbols, and passion only for literature and music of a certain kind; so many beings needlessly discouraged, faltering and baffled in the struggle for life."

ANTI-CHOLERAIC INOCULATION.

THE *Lancet* publishes the following communication from Haffkine, reporting upon his work of anti-choleraic inoculation:

"Anti-choleraic inoculations continue to occupy all my time, and the process has now been applied to about 16,000 persons. I try to work on as large a scale as possible, because it is impossible to know beforehand in what part of the country cholera will make its next appearance. I append the names of the places where inoculations have been freely made up till now: Agra, Alligarh, Lucknow, Delhi, Sanawar, Karsauli, Dagshai, Patiala, Rajpooorah, Chirat, Jhansi, Simla, Jatagh, Rawal-Pindi, Murree, Abbottabad, Peshawur, Sangrur, Nowshera, Naini-Tal, Almora, Ranikhet, Dworahat, Kainur, Pauri, Sakniana, Mussa Gali, Srinagar (Garhwal), Tehri, Mussoorie, Dehra Dun, Hardwar, Lahore and Meen Meer. In all these localities it has been attempted to make the inoculations upon persons who are living in precisely the same environments as their uninoculated fellows; that is to say, I have selected half of a regiment, of a school, of a prison, or of a village for treatment. A record of the names, social position and surroundings, symptoms which appeared, etc., has been carefully kept of each case, with most minute details, and copies of these records have been given to the medical officers in these localities; and it is from these gentlemen that I hope to receive clinical observations upon the subjects of operation when next an epidemic appears. The constitutional

differences displayed by man with regard to cholera are so large that no experience gathered from one, two, or ten individual cases would give even the most general result; the probability being that all the ten selected persons might be constitutionally incapable of being affected by the disease in the recognized manner. On the other hand, operations on animals on account of the particularity of the symptoms which result, are always open to discussions. The results of experience now placed before the eyes of the medical service in India, will bring about, I hope, in the near future a direct revolution in our ideas of the nature of cholera and the means of combating the disease."

A MEMORIAL SKETCH.

WILLIAM F. HUTCHINSON, M.A., M.D.

DR. WILLIAM F. HUTCHINSON died suddenly on September 30, 1893, at Providence, R. I. He had spent the whole day in the usual routine, practising and writing letters, and after dinner made a social call.

He had organic disease of the heart, and several times has had attacks in consequence, in which he was attended by his friend, Dr. Remick. Dr. Hutchinson was sick only fifteen minutes, being conscious to the last. He greeted his medical adviser pleasantly, saying, "Too late this time, I feel I am going, it is filling up gradually, I cannot breathe."

These were his last words, after which he expired, without a struggle, genial and social till the last, just as his life had been. Our departed friend was so talented that it is impossible to say where he excelled most. He was a jovial companion, a true friend, a linguist, a journalist, a tourist, a patriot, a scientist, a true physician and as a specialist an authority in electricity.

He was the friend of his patients, and prominent in all public benevolent enterprises of the day; as a citizen, he was scrupulously honest, generous, and public-spirited, warm-hearted, cordial and genial. As a Freemason he had received the thirty-third degree.

Dr. Hutchinson was born in Oswego, N. Y., October 28, 1838. His collegiate education was obtained at the University of Pennsylvania; and after receiving the Bachelor's and Master's degrees at that institution, he pursued the study of medicine at the Buffalo Medical College and also abroad in the most celebrated of the French and German universities.

Since the close of his student career his life has been a most active one in the service of his country, in both army and navy, in the work of his chosen profession, in literature, art and travel.

He was a linguist, and had travelled much, in fact, had been almost everywhere, particularly in Germany and the West Indies. His memory was wonderful; he could advise about all routes in travelling with more exactness than an excursion agent, tell the time-tables, best ways to take, the names of hotels and their charges. In the West India Islands he was acquainted with every place and everybody, and even could tell of individuals, their habits and their state of health.

As a patriot he was a veteran of the army and navy, and thereby became a member of the Loyal Legion. When the Civil War broke out he went to the front with the Twenty-second Regiment of New York Volunteers, as Assistant Surgeon, in May, 1861. At the battle of Antietam, while giving a drink of water to a wounded Confederate soldier, Dr. Hutchinson was struck by a bullet just over the heart.

At the first battle of Bull Run he was taken prisoner of war; and from July 21, 1861, spent nine weeks in Libby Prison, when he used an opportunity to escape. He participated in the battles of Cedar Mountain, Rappahannock, Catlett's Station, Yorktown and South Mountain, Antietam and second Bull Run. At the latter place he was captured

again, but escaped three days after. He was promoted August 18, 1862, to Surgeon and later to Brigade-Surgeon. He was in charge of Falls Church U. S. A. General Hospital from March to August, 1862, also Provost-Marshal of Fairfax County and commanding Post at Falls Church; on duty at the office of the Surgeon-General and at U. S. A. General Hospital, Portsmouth Grove, R. I. He was wounded several times, and as a consequence suffered every winter afterwards during his life, which necessitated a sojourn in a warmer clime. For this reason he generally spent two months from January in some parts of the West Indies.

On April 13, 1863, by act of the War Department, he was discharged from the army with the rank of Colonel, and transferred to the navy as Acting Past-Assistant Surgeon on the sloop-of-war *Vincennes*. He remained with this branch of the service throughout the remainder of the war. Next he was on the U. S. frigate *Potomac* at the siege of Port Hudson, La., at siege of Vicksburg, and at the battle of Mobile Bay, where he was wounded and taken prisoner again. From the navy he was honorably discharged in December, 1869.

The next four years of his life were passed at Minneapolis, where he acquired an extensive practice.

In 1873 Dr. Hutchinson came to Providence, where he has since resided, except for his frequent European and South American trips. He made electricity a specialty.

He was Assistant Secretary-General of the Pan-American Medical Congress, the organization of which society owed much to his efforts, as he was the representative who brought about the co-operation of the medical men in the Spanish American countries. He was also Vice-President of the American Electro-Therapeutic Association and a Fellow of the Société Française Electro-Thérapeutique.

As a journalist he was considered particularly clever, and for a considerable time was attached to the regular staff of the *Star and Press*. He was formerly an editor of the old *American Magazine*; and up to the time of his death he was the associate editor of the following periodicals: *New England Medical Monthly* and *The Prescription*, *The Times and Register* (Philadelphia), and *Journal of Bacteriology* (New York).

He has written many valuable editorials and other medical articles, one of his last was "Electrical Anæsthesia by means of the Singing Rheotome," and also a text-book, "Practical Electro-Therapeutics," which has had a large circulation. Among his other works are many interesting novels and volumes of travel in South America. His principal work was "Under the Southern Cross." His style of writing is vividly descriptive, and very interesting to read.

Dr. Hutchinson was a prince of good fellows, and moved in the best society. He had been one of the best known men in Grand Army circles. Immediately after his arrival in Providence, he joined Slocum Post, and afterwards became its commander. Later he organized Arnold Post, of which he was also commander for several years. He was a member of the Rhode Island Historical Society, of the Rhode Island Medical Society; and at the organization of the medical department at Tufts College he was chosen a professor.

The funeral of Dr. Hutchinson took place at Providence on Tuesday, October 3d, with military honors. After prayer by the Rev. Mr. Bassett at the house, 78 Mawney Street, at 2 o'clock his remains were taken to the Church of the Epiphany, where the funeral service was held. After all the seats in the church had been filled, Rev. Mr. Bassett and Chaplain Webb escorted the remains to the altar, and the two ministers proceeded with the Episcopal burial service. The solemn rite was very impressive by additions of very tasteful organ preludes and singing of a male quartet. Beautiful flowers covered the coffin. After the service the military cortège followed the remains to Pocasset Cemetery, where the burial service of the Grand Army Veterans was held and the body placed in the earth with the customary military honors.

ROBERT NEWMAN, M.D., NEW YORK.

Correspondence.

THREE UTERINE PREGNANCIES DURING AN EXTRA-UTERINE PREGNANCY.

WORCESTER, MASS., February 15, 1894.

MR. EDITOR:—The enclosed cutting from an old newspaper¹ is certainly curious, and may be interesting to some of your readers.

DIED.

In Uxbridge, Feb. 1, Mrs. Ruth Ellis, wife of Mr. Charles Ellis, 32. It had been her singular lot, for nearly eight years, to have borne an extra-uterine foetus of full size, during which period she had become the mother of three healthy children. Her health evidently declining during the last fall, from its presence, no alternative seemed to be left but its removal, which was effected on the 31st of December, by the Doct's. Miller, of Providence, R. I., and Franklin, Ms. The subsequent discovery, however, of a free communication, which had been previously formed by ulceration, between the small intestine and the sac, and by which all nutriment, received into the stomach, passed through the artificial opening, destroyed all hopes which her physicians, at the successful termination of the operation, may have been disposed to entertain of her eventual recovery. Her sufferings were less than before the operation, but emaciation progressed rapidly; and became extreme, and she at length sank. Her life having been doubtless prolonged by the serenity of mind and calm resignation with which she awaited her fate. (Com.)

I have not found any record of the case in text-books and monographs. Very truly yours,

GEORGE E. FRANCIS, M.D.

¹ The Massachusetts Spy, Worcester, Second Month (Feb.) 10, 1841. Its motto was, "The liberty of the press is essential to the security of freedom."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, FEBRUARY 10, 1894.

Deaths reported 2,718; under five years of age 768; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fever) 342, acute lung diseases 570, consumption 313, diphtheria and croup 160, scarlet fever 42, diarrhoeal diseases 38, measles 33, typhoid fever 23, whooping-cough 16, cerebro-spinal meningitis 11, small-pox 9, erysipelas 8.

From measles New York 19, Milwaukee 8, Philadelphia 5, Brooklyn 1. From typhoid fever Philadelphia 5, Washington 4, Boston, Cincinnati and Cleveland 3 each, Charleston, Worcester, Fall River, Lynn and Quincy 1 each. From whooping-cough Boston 4, New York, Philadelphia and Brooklyn 3 each, Cincinnati 2, Cleveland 1. From cerebro-spinal meningitis New York 5, Worcester 2, Cleveland 1. From small-pox New York 9. From erysipelas Brooklyn 4, New York 2, Philadelphia and Boston 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending February 3d, the death-rate was 20.0. Deaths reported 4,012; acute diseases of the respiratory organs (London) 385, whooping-cough 158, diphtheria 109, measles 54, scarlet fever 45, fever 41, diarrhoea 34, small-pox (Birmingham 5, West Ham 2, London, Bradford and Gateshead 1 each) 10.

The death-rates ranged from 13.3 in Blackburn to 29.2 in Liverpool; Birmingham 20.9, Bradford 16.5, Croydon 14.4, Hull 23.8, Leeds 18.6, London 19.4, Manchester 19.4, Newcastle-on-Tyne 17.6, Nottingham 17.7, Portsmouth 18.9, Sheffield 18.6, Sunderland 16.5.

METEOROLOGICAL RECORD,

For the week ending February 10, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 10, 1894, TO FEBRUARY 16, 1894.

Leave of absence for one month and ten days, to take effect upon the adjournment of the Eleventh International Medical Congress, to be held at Rome, Italy, March 29 to April 5, 1894, is granted COLONEL JOSEPH R. SMITH, assistant surgeon-general.

Leave of absence for one month is granted CAPTAIN REUBEN L. ROBERTSON, assistant surgeon, U. S. A., with permission to apply for an extension of one month.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 17, 1894.

A. F. PRICE, surgeon, ordered to the Torpedo Station, Newport, R. I.

H. E. AMES, surgeon, detached from Torpedo Station and to the "Richmond."

M. W. BARNUM, assistant surgeon, ordered to temporary duty on the "Ranger." Upon the reporting of relief detached from the "Ranger," ordered home and wait orders.

G. T. SMITH, passed assistant surgeon, detached from Naval Hospital, Chelsea, and ordered to the "Ranger."

M. R. PIGOTT, assistant surgeon, detached from "Richmond" and to Naval Hospital, Chelsea.

T. B. BAYLEY, passed assistant surgeon, detached from the "Machias" and to the "Richmond."

DEATH.

JAS. F. KRENEY, passed assistant surgeon, died on board the U. S. S. "Ranger," February 10, 1894.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held at the Medical Library, No. 19 Boylston Place, on Monday, February 20, 1894, at 8 o'clock, P. M.

Dr. E. N. Whittier: "Digestive Paresis." Discussion opened by Drs. E. G. Cutler and W. W. Gannett.

Dr. J. G. Mumford: "Compound Fractures." Discussion opened by Drs. A. T. Cabot and R. W. Lovett. Dr. Goldthwait will show a new method for the direct fixation of the fragments in severe fractures of the long bones.

Dr. J. H. Wright will show cultures from "Gonorrhoea." Members are requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., Secretary.

HARVARD MEDICAL SCHOOL. EVENING LECTURES.

The next lecture will be given on Wednesday evening, February 28th, at 8 o'clock, by Prof. E. S. Wood. Subject, "Urinary Diagnosis." Physicians are cordially invited.

RECENT DEATHS.

SAMUEL MAGNER DONAYON, M.D., M.M.S.S., died in Quincy, Mass., February 19th, aged forty-two years. He was town physician of Quincy for a number of years and was appointed City physician the first year of municipal government, and held the position to the time of his death. He was one of the visiting physicians to the Quincy City Hospital.

AUGUST HIRSCH, M.D., professor of special pathology and therapeutics and of the history of medicine in the University of Berlin, died January 28th, aged seventy-seven years. His great renown was gained by the publication in 1859 of his invaluable hand-book of "Geographical and Historical Pathology." Subsequent to this he was a member of several German Scientific Commissions, notably the German Imperial Cholera Commission in 1873. He represented the German Government at the International Sanitary Conference at Vienna.

FRANCISCO ALONZO RUBIO, M.D., professor of obstetric medicine in the University of Madrid, died recently. He was President of the Royal Council of Public Health, President of the Royal Academy of Medicine and perpetual President of the Spanish Gynecological Society.

CASE OF FATAL HÆMORRHAGE FROM THE LEFT LATERAL SINUS, CAUSED BY A BLOW ON THE JAW.

A. H. L., a tall, athletic student, aged nineteen, was struck in a friendly sparring bout upon the left jaw by the right hand of his opponent. The blow was delivered very nearly straight from the shoulder, and over the uplifted hands of the recipient, whose head was bent forcibly backward by the impact. The fist in striking was pronated. Large gloves were used. The patient on receiving the blow commented in a natural manner upon its excellence, and asked with which hand it had been struck; immediately after this he said that he felt queer, then put both hands to his head, jumped up and down several times, reached out his hand for the wall, staggered and fell unconscious. The accident occurred about five in the afternoon, Tuesday, February 13, 1894.

Efforts at resuscitation on the part of the students proving ineffectual, Dr. Lamarche was summoned, who advised removal to the patient's room. From this time on consciousness was not recovered. The breathing became stertorous; the pupils were first dilated, then contracted. Within about four hours rigidity had appeared in all four extremities, preceded by restlessness. Drs. J. L. Hildreth and J. Homans were called in consultation. The rigidity became more marked, the toes at midnight being drawn down violently. At one o'clock in the morning Dr. Walton was called to advise regarding localization and operation. Dr. Pease was also summoned to assist in case of operation. The condition at this time was as follows: all four extremities were in a condition of tonic rigidity, the legs stiffly extended, the feet in a condition of plantar reflexion, the left great toe being in addition drawn up spasmodically. Clonic movements of the right hand were also superimposed upon the tonic rigidity of this extremity. The elbows were flexed, the hand clenched with the thumbs inward. There was no trace of spasm or paralysis of the face. The eyes were turned somewhat to the left, without strabismus. The pupils were alike, reacting only slightly to light. The neck was flexible, and there was no apparent irregularity of the cervical vertebræ. The unconsciousness was complete; the breathing heavily stertorous, abdominal, with moaning on expiration. There was a tendency to Cheyne-Stokes respiration. Both pupils were large, the left perhaps a trifle the larger. There was a tendency to lateral nystagmus. The knee-jerk could not be obtained on account of the position of the limbs, but continual ankle-clonus was present. There was no priapism. The pulse was 96, full and strong. The temperature was 101°. There had been no bleeding from the nose or ears, no subconjunctival hæmorrhage.

It was concluded that a large hæmorrhage had taken place, involving the base of the skull and extending into the vertebral canal. The most probable starting-point of the hæmorrhage was deemed a fracture of the left glenoid fossa from the impact of the condyle of the jaw, an adjacent vessel being ruptured. Operation was seriously considered, but was decided to be inadvisable, as there seemed no chance that the essential part of the clot could be removed, namely, that pressing upon the pyramidal tract in the medulla oblongata, an opinion borne out by the autopsy.

The condition remained practically unchanged until the next morning. The ice-bag had been applied to the head, counter-irritants and heat to the lower extremities.

Wednesday (second day) spasms recurred at 4.45 and 5.30 A. M. At 7.30 the patient was breathing quietly, the eyes slightly open. There was profuse perspiration. Temperature 102.2°, pulse 100, respiration 28. At 8 A. M. all extremities were still rigid, the rigidity in the right arm and leg being most marked, with spasmodic tendency in these parts. The pulse varied from 76 to 90. At noon the breathing was still quiet, with slight snore on inspiration and low moan on expiration. The pupils were now somewhat dilated, alike. During the afternoon the pupils were widely dilated. The rigidity remained the same, with slight twitching of the right hand. The head was drawn somewhat to the left. The temperature fell to 101.2°. During the night of this day the rigidity lessened; the pupils were widely dilated, and responded slightly to light. The urine had been passed involuntarily before the catheter was used. The jaws were less rigid, but the patient could not swallow. The head was turned somewhat to the left, the eyes markedly so. Attacks of choking occurred during the night.

Thursday (third day) the temperature rose to 102°, the respiration to 30. Breathing stertorous. Head straight. About four ounces of urine drawn. The rigidity had entirely disappeared, leaving all four extremities almost completely relaxed, and paralyzed. The knee-jerk absent. Nutrient enemata not retained.

Operation was carefully considered on this day, Dr. M. H. Richardson being called in consultation regarding this point. It was again decided inadvisable, for the reasons already stated.

Friday (fourth day) the condition had remained unchanged, excepting that twitching of the right eyelid and right angle of the mouth had appeared, with slight spasm of the left upper lip. Very slight spasm of the right leg and hand appeared at the same time. The knee-jerk was absent. The pupils were alike, rather small, the eyes turned somewhat to the right, the left not following perfectly. At 11 A. M. the respiration was very shallow; the pulse varied from 58 to 84. Enemata were retained. The catheter showed the bladder empty. During the preceding night the respiration had been very irregular, at times sighing in character. The eyes had turned sometimes to the right, sometimes to the left. Every half-hour there were short cessations of breathing, followed by spasmodic cough, with intermittent pulse, rising to 90, then falling to 48. Respiration 50.

Saturday (fifth day) the condition remained much the same; the patient gradually failing; the temperature rising in the afternoon to 105°, dropping back to 104°; the pulse rising to 130 and becoming very feeble.

Sunday (sixth day). Patient steadily sinking; temperature rising in the afternoon to 106.4°; hands purple. Patient died quietly at 3.50 P. M.

The autopsy was made the following morning by Medical Examiner Swan, Drs. Councilman, Homans, Hildreth, Durrell, Walton, F. W. Webber (of Newton), Pease, and G. W. Fitz (of Cambridge), being present. The result of the autopsy was as follows:

Body of a spare, muscular, well-built young man. Rigor mortis present. Lividity of dependent parts. No external marks of violence. Head opened. Subcutaneous tissue of scalp shows no evidence of injury.

Calvarium removed. Surface of brain covered with extravasated blood beneath dura, (most marked over occipital lobes,) of blackish color and tarry consistency; greatest quantity on the left side. On removing brain, middle fossa on left side found to contain several ounces of the same black, tarry blood, and base of brain covered with the same (filling the posterior fossa and extending into the vertebral canal). There was a small rent in the lateral sinus near outer margin of temporal bone. About this rent, for a short distance, the dura mater was dissected up. No fracture of upper part of skull or upper cervical vertebrae. Brain, on section, showed marked injection of blood-vessels and flattened convolutions; otherwise normal. No extravasated blood or fluid in ventricles.

Pleura everywhere smooth and glistening. *Lungs* large, soft. On section, upper part of lungs dry and crepitant. Much dark and frothy fluid flowed from middle and lower portion of lungs (œdema). *Pericardium* smooth and glistening. *Heart* normal size. Walls of right ventricle slightly thicker than normal. Valves smooth and soft. *Aorta* smooth, soft and elastic, and measures only six and one-half centimetres, just above the aortic valve. *Peritoneum* everywhere smooth and glistening. *Stomach* contains a little dark, slimy mucus. Small intestine contains small amount of yellowish, gruel-like material. *Large intestine* contains gas and lumps of small, yellow faeces. Mucous membrane throughout normal. *Liver, spleen and kidneys* engorged with blood, otherwise normal. *Pancreas* normal. *Bladder* contains a little turbid urine. Great vessels of trunk contain dark liquid and clotted blood.

Diagnosis, rupture of lateral sinus and resultant hæmorrhage, caused by blow on head.

REMARKS (DR. G. L. WALTON).

On account of the widespread interest in this unfortunate case, and in consideration of the general desire on the part of practitioners to know the exact facts, it was thought best to publish the account at once, without attempting a review of sparring accidents in general, the collection of the necessary data for which would require considerable time. A *résumé* of the important points at issue will not, however, be out of place.

On holding to the light the base of a skull, from which the calvarium has been removed, it will be seen that the roof of the glenoid fossa, which receives, on either side, the condyle of the jaw, is extremely thin. Cases are on record, and specimens preserved, in which blows upon the jaw have produced fracture at this point. The condyle has been found in one such case driven directly through the skull. Study of the parts would lead one to expect this accident with comparative frequency if the condyle were not so placed that the violence of such a blow is quite as apt to be distributed to the sides (more particularly to the posterior and inner walls) as to the roof of the glenoid fossa. In fact, the violence of most blows upon the jaw, upon the chin, for example, would naturally be so far distributed in other directions (upon the teeth, or through the superior maxillary bone) to say nothing of the mobility of the jaw itself, and its liability to fracture, that it must be only in a very exceptional case that the full force of impact is transmitted to the roof of the glenoid fossa.

Rarely as fracture occurs in this locality from this cause, it is probably even more unusual for a blow of

this nature to produce hæmorrhage without fracture. Assuming the vessel wall to be healthy (and the autopsy revealed nothing to the contrary) the most plausible explanation in this case seems to be that if the force of the blow was expended on the jaw it was directly transmitted to the posterior upper wall of the glenoid fossa (firm bone), thence through the zygoma and petrous portion of the temporal, expending itself, by a species of *contre coup*, upon the point of least resistance on the other side of the bone, namely, the thin wall of the adjacent sinus. This course would follow an uninterrupted path of solid bone; which broadens into the petrous portion of the temporal, and furnishes a buttress well fitted ordinarily to withstand blows from this direction. The term *contre coup* should not be here confounded with its ordinary surgical usage, for there was no indication that any hæmorrhage, contusion, laceration, or other lesion, was produced upon the opposite side of the cranium.

Possibly the compression of the jugular vein may have caused sudden tension in the sinuses, contributing to the result.

It will not be out of place briefly to discuss the localizing symptoms and the question of operation, vital considerations in this class of cases.

In the first place, regarding the nature of the lesion, all the general symptoms pointed to hæmorrhage. The fact that the patient was not momentarily stunned (as shown by his remarks on receiving the blow) ruled out concussion in the ordinary surgical acceptance of the term. The onset of reeling, falling, loss of consciousness, deepening stupor, stertorous respiration and full pulse, with alteration of pupils, pointed conclusively to the pouring out of blood; the severity and fulminating character of the symptoms indicating a hæmorrhage of rapid onset and considerable extent.

With regard to the seat of the clot, convulsive rigidity of arms and legs pointed to implication of the motor tracts of these members somewhere in their course, or to their cortical centres, the absence of facial involvement showing the escape of the facial centres and tracts. Hæmorrhage into the internal capsule could at once be ruled out by the bilateral nature of the symptoms from the first. The only accessible regions left to consider were the motor centres for the arms and legs on the cortex, the *crura cerebri*, and the pyramidal tracts at the base, especially in the medulla oblongata, where they come to the surface.

In the case of bilateral symptoms resulting from unilateral pressure on the cortex (for example, in cases of middle meningeal hæmorrhage, with transmitted pressure to the opposite side) the onset of symptoms is always unilateral. Supposing, again, so improbable a lesion as double middle meningeal hæmorrhage from a blow of this nature, the facial centres could hardly escape.

At the base, however, we find the fibres for both upper and lower extremities for the two sides running so closely together that involvement of all four limbs would be the natural consequence of hæmorrhage pressing upon this region. The facial nerves having left the motor tract above the pyramidal crossing, would explain the absence of facial spasm and paralysis, in case the bulk of pressure was brought to bear at this point. We have only to suppose that the facial nerve in its course, escaped sufficient pressure to cause paralysis, a not unreasonable theory, considering the comparative immunity of basal peripheral

nerves sometimes observed in cases of even extensive basal exudation. The ocular nerves were certainly almost free from implication in their course along the base. It is especially noteworthy that there should have been no paralysis of the abducens, for the long course of this nerve over bony irregularities renders it especially liable to pressure, so much so that internal strabismus sometimes results from pressure downwards of the brain itself, caused, for example, by a large tumor in its substance.

While it might be conceivable that convulsive symptoms from irritation of the cortex should result from pressure at the base, this seems a hardly probable supposition, and in any event the symptom-complex should have included facial spasm.

The most reasonable explanation of the rapid onset of convulsive rigidity of all extremities, with ankle-clonus, seemed, therefore, that irritation of the pyramidal tract in the medulla was quickly produced by the hæmorrhage, the succeeding paralysis with relaxation resulting from loss of conduction through these tracts on account of the extreme pressure of the clot.

Let us now consider the other symptoms in the order of their localizing value. The occasional slight difference between the pupils, in favor of the left, was due to paresis of the third nerve on that side, from pressure of the clot in the middle fossa extending to the sphenoidal fissure, as pointed out by Hutchinson,¹ in cases of middle meningeal hæmorrhage. The temporary weakness of the internal rectus, shown by the left eye not perfectly following when the eyes were deviated to the right, points to the same pressure on the left third nerve.

Conjugate deviation of the eyes, as well as bilateral dilatation and contraction of pupils, are common in various lesions, and furnished very little assistance as localizing factors in this case.

With regard to the conjugate deviation, the direction was generally to the left while convulsive symptoms were present, this condition alternating with deviation toward the right when paralytic symptoms ensued. This fact would tend to negative the view that the symptom was due to extension of the clot to the centre for conjugate deviation in the angular gyrus. In this event the extension would naturally be more marked on the left than on the right, and would seem rather to turn the eyes to the right than to the left, since deviation *away from* the lesion is the rule in case of cortical irritation, *towards* the lesion in that of cortical paralysis.

Irritation and paralysis of the sixth nucleus in the medulla oblongata cause, respectively, conjugate deviation toward and away from the lesion through fibres connecting the sixth nucleus of one side with the third of the other; this nucleus is, however, so far removed from the surface, that is, in the floor of the fourth ventricle (where no evidence of lesion existed) that the pressure of a clot at the base could hardly be expected to cause such irritation and pressure, at least, affecting the nucleus on either side alone. A centre for conjugate deviation also exists in the second frontal convolution, which may or may not have been directly or indirectly affected by the extension of the clot. In point of fact conjugate deviation is a symptom so readily provoked by lesions in various localities, as well as in cases without recognizable local lesion (as in simple epilepsy) that it is of compara-

tively little value as an absolute guide to localization, though sometimes valuable as a corroborative element in diagnosis.²

The comparative rapidity of the pulse in spite of the extreme degree of compression, while possibly merely an accompaniment of elevated temperature, may have denoted paresis of the pneumogastric.

Analogous cases can hardly be adduced to throw light on this one, for, as far as we know, we have to do with the first instance on record of this exact injury.

An unfortunate coincidence of hæmorrhage at the base and a blow received in sparring, occurred in 1884, at New Haven. The physicians differed as to the probability of fracture. It was said, however, by observers of the bout, that the young man commenced to fall before the blow (upon the forehead) was struck. Dr. Foster writes Dr. Hildreth regarding this case, that stupor and paralysis of all the extremities followed, and that death ensued six days later. No fracture was found, and Dr. Foster, who had disbelieved in fracture from the first, regarded the blow merely coincident, not causal, the apoplectic attack being precipitated, in his opinion, by excitement. This case comes, therefore, under a different category.

No report of autopsy after death from a blow upon the jaw has come as yet to our notice, though we are informed that this is not the first instance of such unfortunate result.

Cases of hæmorrhage following blows directly upon the head, without fracture or predisposing arterial disease, are already sufficiently rare to be worthy of publication, but that such a blow as here received should produce this result, would seem almost impossible were the fact not demonstrated by such a case as the one under consideration. The occurrence must be regarded, therefore, as a rare result of a chance blow, which could not have been foreseen and which may never occur again.

With regard to the question of operative interference: Had the symptoms pointed to middle meningeal hæmorrhage of the usual seat, whether upon the side upon which the blow was struck or upon the opposite side, the advisability of operation would have been at once established. The symptoms of this lesion are sufficiently well marked, and the successful issue of operation sufficiently well established, to place this contingency among the well-recognized indications for surgical interference. The same is true of hæmorrhage from the middle cerebral artery, the symptoms in this event being identical, the seat of the clot being practically the same, except that it is subdural instead of extradural. The chief localizing symptoms in both these lesions are spasmodic movements of the opposite side of the face, and of the opposite arm and leg, followed by hemiplegia, the symptoms later becoming bilateral. Such symptoms may be delayed, a period of perfect consciousness intervening after the stunning effects of the blow have passed away and before the deepening stupor of hæmorrhage ensues. In one such case under Dr. Homans's care, reported in the *Boston Medical and Surgical Journal* (February 12, 1891) spasm of the right angle of the mouth preceded by aphasia and followed by convulsions involving the right arm and leg, becoming rapidly general, appeared seven days after a fall upon the right side of the head.

¹ On Compression of the Brain, London Hospital Reports, 1867.

² See Vierordt (Diagnostik der Inneren Krankheiten, s. 541) on the Localising Value of Conjugate Deviation.

Hæmorrhage by *contre coup* was diagnosed, and the clot successfully removed at my suggestion by Dr. Homans, perfect recovery following. The hæmorrhage was subdural and involved the motor tract and temporal region, most copious over the facial area.

In the present case we had to do with a hæmorrhage in such location, and so quickly poured out, that by the time the symptoms were sufficiently marked to point with any definiteness to the seat of the lesion, the base of the skull had been flooded, and the vertebral canal so far invaded as to cause severe pressure upon the medulla oblongata. The only excuse for operation here would seem to be the otherwise hopeless condition of the patient. Upon this point the personal equation varies greatly, but the prevailing feeling among the consultants in this case was that while any hope of relief, however faint, would justify the attempt in so desperate a situation, there was really absolutely no prospect of relief by surgical interference. The patient was on the verge of death, which the shock of operation might only precipitate, and remove the remote (certainly extremely remote) possibility of absorption. Ligature of the carotid artery was hardly advisable. This procedure, aimed to control, for example, middle meningeal hæmorrhage, though proposed by Forneaux, Roser, Simons and others,² promises very little in these cases, as shown by Gallez³ in his recent contribution to the study of trephining, who points out that the hæmorrhage is not always controlled in this way, and that even if it be controlled, the consequences of the clot are not averted.

The question of trephining for hæmorrhage at the base, with or without fracture in this location, is one upon which study is not exhausted. Possibly future experience may lead to less conservatism in this class of cases, but we do not gain sufficient encouragement from the present status of cerebral surgery to afford hope that drainage of the base of the skull, difficult at the best (particularly on account of pressure downwards of the cranial contents) can be satisfactorily established in so desperate a case as this, in which the vertebral canal has been already invaded.

Gallez,³ in commenting upon this point, after speaking of the comparative hopelessness of operations for very extensive hæmorrhage, uses the following language: "It is even less justifiable to undertake operation when symptoms exist of compression of the bulb, and of the nerves at the base of the brain; dilatation and paresis of the pupils, or rapid pulse (caused by paralysis of the pneumogastric). The extravasation is too diffuse."

Jacobson and Agneau are quoted by this writer in substantiating this view, the former authority adding that the condition points to extensive fracture. This would certainly in a majority of cases be true, and was to have been expected in our case, but whether fracture were present or not, the contra-indications to operation for hæmorrhage of this extent and seat, would seem absolute.

The autopsy, in the opinion of all present, certainly justified the conclusions drawn, both regarding the localization and the question of operation, the vital points in the case. The existence or non-existence of fracture had comparatively little practical bearing, either on the diagnosis, prognosis or treatment.

MALIGNANT DISEASE OF THE RECTUM.¹

BY GEORGE W. GAY, M.D.,
Surgeon to the Boston City Hospital.

THE brief paper which I venture to present to you to-night is a sort of running commentary upon some of the salient points of this disease and upon some of the cases met with in my practice. As there is no known permanent, radical cure for these affections, our efforts are necessarily directed to the management of the cases with a view to prolonging life, and to making it as endurable as possible while it lasts.

The first point to receive consideration in all diseases of the rectum is the diagnosis. I should not feel called upon to advise and to urge upon the younger members of this Society the very great importance of a digital and visual examination, had I not seen and made some very embarrassing mistakes by neglecting this important essential. Every hospital or consulting surgeon has met with cases of malignant disease of the anus and rectum which have been treated as piles, simply because no proper examination had ever been made.

A noted musician, whom the older portion of this community remembers with pleasure, came into my office some years ago, saying that he had the piles, and had been treated for them off and on for two or three years. He wanted to know what was the matter with him. I was shocked at his appearance; emaciated, sallow, weak, a wreck of his former robust self. A digital examination revealed a large mass of malignant disease situated just above the internal sphincter, which any one could easily have found, and the character of which could not have been mistaken for anything else. It need not be said that I received much undeserved credit in the case by simply telling him his real condition.

As further showing the importance of making a careful examination in cases of suspected disease of the rectum, I may allude to the case of a woman who was brought to me by a reputable physician for an opinion as to the character of a rectal tumor which he had detected by a vaginal examination alone. Epsom salts and warm-water injections removed the lump in a few days.

Both of these mistakes could have been easily avoided by simply making a digital examination of the rectum. The diagnosis should never be made upon subjective symptoms alone. The external parts should be carefully inspected, and the finger should be carried as far up the rectum as possible. A lady was put under my care several years ago by Dr. Brainard, for the removal of a small patch of malignant disease situated nearly or quite five inches from the anus. It was reached with difficulty by the finger, and a careful, thorough search was necessary for its detection. Hæmorrhage was the principal symptom.

A woman about fifty-two years of age is under my care at the present time, who for several weeks had pelvic pain and colic, which were greatly aggravated by laxatives or cathartics. Constipation was obstinate. Repeated vaginal and rectal examinations revealed only a uterine fibroid on the posterior surface of the womb, which, it was thought, might be the cause of the pain and constipation through pressure. Etherization relaxed the parts, so that this explanation was at once

¹ Lancet, 1885; Medical Times, October 17, 1883, page 548.

² La Trepanation du Crâne, Paris, 1893.

³ Loc. cit., page 272.

¹ Read before the Boston Society for Medical Observation, January 1, 1894.

abandoned, and a fibrous stricture was detected, as far up the rectum as the fingers could be carried. It was annular, movable, firm, not hard nor nodular. Its character may be inferred from the fact, that the symptoms were promptly ameliorated by inunctions of oleate of mercury, and the administration of iodide of potash. These cases are sufficient to show the importance of a thorough digital examination.

The last case leads me to speak of the great value of an anæsthetic in all rectal affections located above the sphincters. Except in very thin people with lax tissues, it is not possible to make a thorough and satisfactory examination of the pelvic organs without an anæsthetic. This rule is emphatically true, as regards affections of the rectum. With the patient under ether in the lithotomy position, the sphincters are to be thoroughly stretched, and the rectum cleared by an enema if necessary. A digital examination can now be made to the best advantage to detect strictures, growths or ulcers. With a Sims's speculum and a horizontal light, a good view can be obtained of from four to six inches of the lower part of the rectum, which is the location of nine-tenths of its lesions.

Bougies, sounds and catheters are of little use in making a diagnosis of stricture of the rectum. They impinge upon the promontory of the sacrum, or get caught in a fold of the mucous membrane, thereby giving untrustworthy evidence as to the true condition of the part. The finger is the only reliable sound, and the diagnosis of those rather rare strictures located above its reach is to be made from the symptoms, such as colic, abdominal distention, etc.

The majority of abnormal growths found in the rectum of adults are either specific or malignant in character. Aside from these causes, strictures may be due to tuberculous or other inflammatory changes, or they may be traumatic in character. Neoplasms or strictures due to other causes than cancer or venereal disease, are not very common in our metropolitan hospitals. Dr. Kelsey, in the late edition of his admirable work upon diseases of the rectum, makes the statement that almost as many strictures of the rectum, not malignant, are non-venereal as are venereal. Considering the facts, that little dependence can generally be placed upon the therapeutic test of the nature of the affection; that the clinical appearances are not always sufficiently characteristic; and that histories of cases through ignorance, carelessness, or wilful deception, are proverbially unreliable, I am unable to understand this statement. Specific and venereal diseases permeate society to such an extent, and are met with in such unexpected places, that the older practitioners, who have seen a good deal of these affections, will hesitate to subscribe to the above statement.

I venture the assertion that strictures of the rectum in adults, non-malignant and non-venereal are not often met with in our large hospitals. It is by no means easy in every instance to decide at once as to which of the two most common classes the patient belongs, but the cases are rare which cannot fairly be ascribed to malignant or venereal causes.

A differential diagnosis is of much importance, as affecting the prognosis and treatment. Specific and other non-malignant strictures may, and not infrequently do, send their owners to the poorhouse; but it is only after many years of suffering that they find rest in the grave. On the other hand, malignant disease of the rectum usually runs its course in two to

three years, and terminates fatally in the vast majority of cases. The exceptions to this rule are so rare, that I have ascribed the recovery in two instances to a mistake in the diagnosis.

When a digital examination reveals a hard, nodular mass in the rectum, more or less immovable, involving the mucous, submucous and adjacent structures, and encroaching upon the lumen of the bowel, there can be little doubt as to the malignant character of the disease. It is safe to entertain the same opinion in cases of hard, ragged ulcerations with indurated edges, and deep attachments. Not infrequently a rather soft, friable upgrowth is met with, which bleeds easily, grows rapidly, and is liable to recurrence.

Malignant disease at the anus resembles epithelial growths in other regions of the body, presenting an ulcerated surface with or without an upgrowth, and having a hard indurated base. The surrounding skin usually presents a healthy appearance, rather than a sodden, fissured, or nodular surface, as is so frequently seen in cases of specific disease in this region.

A broad, general distinction between malignant and specific disease of the lower bowel is, that the latter involves the anus, while the former is located higher up, so that oftentimes an area of healthy mucous membrane separates the disease from the sphincters.

While the therapeutic test is usually disappointing and unreliable, yet occasionally it is very satisfactory. Four years ago I saw, with Dr. Joseph Stedman, a woman under forty years of age who had extensive disease of the rectum above the sphincters, which was hard, indurated, involving adjacent tissues, thereby leading me to express the opinion, that it was malignant in character. She was put upon the compound tincture of iodine, and given an unfavorable prognosis. She took the medicine faithfully for many months, and still continues its use at intervals. She is very well, and has evidently derived great benefit from the drug. In this case the diagnosis was wrong, but the treatment was right.

It goes without saying that the prognosis in malignant disease of the rectum, as in other parts of the body, is unfavorable. While there is no known cure for these affections, yet much can be done to prolong life in many cases, and nearly always to make it more endurable.

The treatment is palliative or radical. I think that the opinion is gaining ground in this country that the former is preferable in very many patients. The operation, or mode of treatment, which cures cancer, has not been discovered. Hence the object of our efforts in the management of the affections under consideration is to give the sufferers all the comfort possible. It does not always seem desirable to prolong life, and yet that is very properly one of the objects of the physician's work.

The treatment of this disease may be considered under three heads, namely: the alterative, the opium, and the operative methods. Whether one or all of these modes of treatment shall be pursued in any given case, depends upon circumstances.

A good illustration of the alterative method was seen in the case of a policeman about forty years of age, who had a malignant ulcerating mass three inches in diameter upon the anterior wall of the rectum above the sphincters. Its location precluded any radical operation, and the symptoms did not call for colotomy. He took from nine to twenty-seven drops of the com-

pound tincture of iodine daily for upwards of two years; once or twice a day he took an enema containing from one to two grains of cocaine. He was thus enabled to do his work as patrolman for the above period. The time finally came when his strength began to fail; and on the day that he was discharged from the force, he went into an adjoining room, and shot himself dead. He fully understood the hopeless nature of his disease; and the moment that he was disabled he took the management of the case into his own hands.

In view of the fact that this man was always better on resuming the treatment, his physicians could not but think, that it had a decided beneficial effect.

It is nearly three years since I removed a growth two inches in diameter from the rectum of a man forty-seven years of age, by Cripps's operation. It was pronounced malignant by competent authority. The symptoms were pain and hæmorrhage. He has taken the iodine daily since the operation, and there has been no return of either symptoms or growth. I dread, however, to see this man enter my office, as I do any other person, upon whom I have operated for cancer; for it is probably only a question of time when a recurrence will take place.

Six years ago I removed a similar growth from the rectum of a middle-aged lady, by Cripps's operation. For four years she took Chian turpentine, and drank Ypsilanti water constantly. There has been no recurrence of the hæmorrhage, or of the disease. I am inclined to ascribe the cure in this case to a mistake in the diagnosis, rather than to the treatment.

Many years ago Dr. Henry M. Field, of Newton, suggested to me the iodine method of treating malignant disease of the rectum. He thought that he had seen beneficial effects from its use; and so far as regards two cases, which I saw with him, I can confirm his opinion. For a long time I have given the drug to nearly all of my patients with malignant disease, wherever located, provided they could take it without disturbing the stomach. In many cases I could not see that any benefit was derived from its use. The rapid growing and markedly malignant ones, as might be supposed, derive less aid from it than others.

The natural course of malignant disease varies so much in different individuals, that it is extremely difficult to arrive at reliable conclusions as to the true value of any drug in checking or modifying the new growths. Chian turpentine, condurango and many other articles have had their day, and have been discarded because they did not stand the test of experience. I do not claim anything for iodine. I use it, because I think it is our duty to give these unfortunate people the benefit of every possible aid; and for this particular purpose, I know of nothing better at present than the compound tincture of iodine.

Sooner or later most patients afflicted with malignant disease of the rectum are compelled to resort to opium to relieve their sufferings. The pain is usually due to obstructed peristalsis, colic as we call it, or to the pressure or other influence of the growth itself upon the nerves. The first is paroxysmal, and is coincident with the vermicular action of the bowels. The latter is a steady, grinding, boring, or aching pain, very wearing to the nervous system, and very distressing to bear. Both can be controlled to a certain extent with opium. Both are relieved temporarily by excision of the growth. Colotomy usually relieves the colic permanently, but may do the pressure-pain little, if any good.

A fair example of the opium treatment was recently under my care through the courtesy of Dr. Whittier. A man, sixty-eight years old, had suffered about two years with a cancer of the rectum. It was located well above the sphincters, hard, nodular, and involving the neighboring parts to a wide extent. Colic and pressure-pains were severe. The liver was greatly enlarged by a secondary growth extending nearly to the umbilicus. Several surgeons were consulted at different times, and all very properly advised colotomy. The patient finally became so weak and exhausted from the progress of the disease, aggravated by the great difficulty experienced every week in his efforts to empty the bowels, that he realized the fact that something must be done. The opium and operative treatments were fully explained to him and he decided to try the former. At first a quarter of a grain of morphine given twice daily under the skin was sufficient to relieve most of the pain. This quantity was gradually increased until he took between three and four grains daily, with the effect of keeping him fairly comfortable. The bowels did not move for nine weeks after he began the morphine. His diet consisted of gruels, soups, and beef extracts. No clear or unmodified milk was given during this period. After some weeks of this complete obstruction, the fæces could be easily felt in the left iliac region. The abdomen never became distended to any extent, although very little flatus escaped for several weeks. The paresis of the intestines produced by the morphia was surprising. There was no vomiting, hiccup, delirium, nor headache. Thirst was urgent, and the mouth and throat were very dry and parched, in spite of all our efforts to prevent it. The emaciation became extreme. The bowels finally began to move of themselves, without aid of any sort; and during the last weeks of his life he had from two to six stools daily, thereby completely removing the collection above the stricture. There was no hæmorrhage. He died from exhaustion. A seasonable colotomy would doubtless have enabled this man to keep about longer, and to have postponed the opium stage for a time. Whether his life would have been prolonged thereby, is a question not so easily decided.

Under the head of operative treatment there are three measures, which require consideration, namely, Cripps's and Kraske's operations and their modifications, and colotomy. The first is particularly adapted for cases in which the disease is limited to the first five inches of the bowel. It consists briefly in dividing both sphincters and rectum as high as the tip of the coccyx, and then dissecting out the growth or diseased tissues.

Judging from a limited experience, this is a very satisfactory operation. The dangers are shock and hæmorrhage. I have never seen incontinence of gas or fæces to a troublesome degree follow this operation. It is especially indicated for the removal of growths which are limited in extent, movable, and not located over the urethra and prostate.

Kraske's operation is designed for the removal of growths located higher up than five inches, or above the reach of the finger. The sphincters are not divided. The bowel is reached through an incision over the sacrum and coccyx. The latter bone and a portion of the former is removed. The gut is divided above and below the diseased portion; the latter is removed; and the ends of the healthy bowel are joined with sutures or fastened in the wound, as the condition requires.

The peritoneal cavity is usually opened in this operation, thereby adding another element of danger from extravasation of feces.

Finally, we come to the most satisfactory operation for the relief of the majority of cases, colotomy. This is now most frequently done in the left inguinal region, for the reason that the operation is more quickly and easily performed, the wound can be attended to far better by the patient, and the danger is no greater than in the loin. The relief to the obstructive pain or colic is usually complete and permanent. The pressure-pain may still require opiates or other treatment. Many lives are prolonged; and, more than that, they are made comparatively comfortable by this operation. In most cases the patient can keep himself clean and free from odor. A woman upon whom Dr. Bradford performed right lumbar colotomy worked for many months alongside another woman, without the latter ever suspecting that anything was the matter with her companion.

Kelsey's description of the operation is the best one I have seen. The incision parallel with Poupart's ligament is made about an inch from the left anterior superior spine. The peritoneal cavity is opened, and the colon brought out of the wound. The "bar" is made by joining the edges of the incision with a silver wire passed underneath the bowel. The intestine is then joined to the edges of the wound with sutures, and two or three days allowed to elapse before the bowel is opened. The operation is neither difficult nor dangerous, and in very many cases it is a most satisfactory one to both patient and surgeon.

By way of recapitulation it may be said, that the treatment of malignant disease of the rectum is essentially palliative. Colotomy is indicated to relieve obstructive colic, and it should be done early in order to save the patient's strength. The radical operations are indicated in the early stage, when the growth is limited in extent, free from deep adhesions and infiltration, and not infringing upon the urethra or prostate. Opium, the king of drugs, is to be avoided as long as possible, and given judiciously, in order that its beneficial effects may not be lost by over-doses before the time comes when it is needed the most. While the disease is incurable, very much can be done by judicious management to make the patient's life endurable and his death peaceful and easy.

A CASE OF PULMONARY STENOSIS IN AN ADULT.

BY OLIVER H. EVERETT, M.D., WORCESTER, MASS.

THE following case is interesting in that the diagnosis was made incidentally, and not because the patient complained of any symptoms pointing to her heart. Furthermore, the rarity of the lesion in an adult makes it worthy of record, as well as the fact that the patient has attained her present age with so few symptoms. Professor Loomis, in reporting a similar case,¹ speaks of it as one of the "curiosities of medicine."

Mrs. X., twenty-seven years old, a native of the State of New York, of French-Canadian parentage, applied for admission to the Memorial Hospital, November 10, 1893, thinking she had typhoid fever, as

she had been taking care of a patient with that disease. She had a slightly elevated temperature, and was admitted for observation. She says she has always been fairly well, though never strong and cannot do hard work without getting tired and out of breath. Even as a girl she could not join in active plays. There is no history of rheumatism, chorea or other disease except scarlet fever and *la grippe*. When she was ten or twelve years old her dyspnea became more marked; and in the course of the next few years she was examined by several physicians, who said she had heart disease. There has been nothing abnormal about menstruation since that function was established at the age of fourteen. Since that time she has never but once consulted a physician for her heart. She was married ten years ago, and has had four children. She has always suffered from cold hands and feet, and occasionally has had slight swelling of the ankles. She does her own house-work, with some help about washing and ironing.

She is a fairly strong-looking woman, of medium height, face slightly flushed, but not cyanotic or livid. Finger- and toe-nails somewhat rounded, and blue (instead of the normal color) under them. On examination of the chest the most striking point is a long inspiration, like a sigh, occurring from three to six times a minute. She says she always breathes in this way, feeling as if she should smother otherwise. The night-nurse reports that there is no irregularity in her breathing when asleep. The apex beat of the heart is faint and diffused, and can be only definitely localized when she is sitting up. It is then found in the mammary line below the seventh rib. No thrill is perceptible over the heart, nor any impulse to be felt below the ensiform cartilage. The heart's dulness begins at the upper border of the fourth rib, thence to the apex beat, and thence to the middle of the sternum. Over most of the cardiac area the heart-sounds are normal, though rather faint, and there is no murmur over the aortic valves. To the left of the sternum, however, in the first, second and third intercostal spaces, is a soft, blowing, systolic murmur. Its point of greatest intensity is in the second intercostal space, close to the sternum, whence it may be traced upwards, and to the left, in a line pointing directly to the middle of the clavicle. Downwards it cannot be heard further than the third intercostal space. The murmur does not disappear on full inspiration. The pulmonic second sound is fainter than normal, and there is no thrill or impulse to be felt over this artery. Percussion and auscultation reveal nothing abnormal in the lungs. Dulness is normal over the liver and spleen. There is no ascites, and no oedema of any part of the body. Superficial veins of legs and upper part of the chest are well marked. There is no pulsation in the jugular veins, nor are they particularly prominent. The radial pulse is small and weak, has ranged between 70 and 90, and is alike on both sides. Examination of the urine shows it to be acid, specific gravity 1.015, and containing neither albumen nor sugar. Since being in the hospital she has once spit up a little blood, or bloody mucus, which I did not see, and have no reason to suppose came from the lungs; but the fact is interesting in view of the frequent termination of such cases in phthisis, with hæmoptysis often an early symptom. Her temperature became normal the next day after her entrance, and she has shown no symptoms of typhoid fever.

¹ International Clinics, 1893, second series, vol. iv, p. 13.

Having now a case of murmur over the seat of the pulmonic valves, the first question is as to its origin. Balfour² says, "The pulmonary area has been not inaptly termed 'the region of romance,'" referring to various interpretations which have been given to murmurs in this location. This is one of the less common situations of cardiac murmurs, which, when present are usually inorganic. Flint³ says an inorganic pulmonic direct murmur is not infrequent, though it seems to be far less common than an aortic inorganic murmur. That the murmur in this case is pulmonic and of organic origin I feel very sure. It is not heard at all to the right of the median line of the chest, nor is it transmitted into the carotids as Flint⁴ says is always the case with an aortic murmur. Neither can it be heard at all towards the heart's apex, nor in the back, as a mitral murmur would be; but can be traced from its point of greatest intensity, upwards and outwards, towards the middle of the left clavicle. All these points show its pulmonic origin. Murmurs in this situation have been ascribed by some authors to mitral regurgitant lesions, heard here instead of at the apex as usual. In accordance with this theory, which has been advocated by Balfour, the murmur comes from the dilated appendix of the left auricle coming close to the chest wall. Such a murmur is differentiated from one arising in the pulmonary artery by its point of greatest intensity being a little further to the left, in such a position that when the stethoscope is placed over it there is at least the width of the tip of the middle finger between the instrument and the left border of the sternum. With a pulmonic murmur the stethoscope, when over the point of greatest intensity, touches, or even overlaps, the sternal border. Authorities differ as to such a murmur being ascribed to mitral insufficiency. Flint dismisses it very summarily, saying the question is hardly worth the discussion which has been given to it. However that may be, there is in the case reported an entire absence of any symptoms pointing to mitral disease, and the murmur is best heard when the stethoscope is close to the sternum.

Now, most pulmonic murmurs are inorganic. Is that the case in our patient? I think not. The color of her skin and mucous membranes is good, and shows no sign of anæmia; there is no venous hum in the vessels of the neck; and the pulmonic second sound is fainter than normal, instead of being accentuated. The heart's dulness on percussion is somewhat increased; and there are positive signs of engorgement of the systemic veins, in the blue finger- and toe-nails, and the venous enlargement in the legs and chest. In addition to these points in the differential diagnosis, Bramwell⁵ mentions the difference in the character of the pulse. In early anæmia it is of good tension, but irritable and variable in rate, while in pulmonic stenosis the pulse is small and weak, and may be intermittent. Furthermore, this patient has had rest, tonics and good food; yet while she feels better than on entrance to the hospital three weeks ago, her murmur is just as clearly marked as at first.

Dr. Nelson, at the Memorial Hospital, has very kindly examined this patient's blood, according to Ehrlich's method, as described by Dr. W. S. Thayer in the *Boston Medical and Surgical Journal* for Feb-

ruary 16 and 28, 1893, and finds no indication of anæmia. Dr. Nelson's report is as follows:

"Red corpuscles normal in size, form and color. Red and white corpuscles in normal proportion. Different varieties of leucocytes are in about normal proportion; neutrophils 75 per cent., eosinophils four per cent., small mononuclears 18 per cent., large mononuclears and transitional forms three per cent."

For these reasons an inorganic, anæmic origin of the murmur may be excluded.

Before considering stenosis of the pulmonary artery as the cause of the murmur, there are some other conditions, which may give rise to it, to be taken into account. When the left lung is retracted, as by adhesions from an old pleurisy or by long standing disease, the pulmonary artery may be in contact with the inner surface of the anterior chest wall, making its pulsation visible and palpable, and producing a systolic murmur. There is no history of any such disease of the lung in this case, nor any physical sign of such a condition now existing. Balfour says that under these circumstances the murmur is produced by compression of the artery between the parietes and the heart in systole; and he describes such a case.⁶ A murmur depending on retraction of the lung disappears on a full inspiration, which is not the case with this patient. Bramwell⁷ speaks of cases where a pulmonic murmur was produced, which he ascribes to a deposit of lymph outside the pericardium, the result of an antecedent pleurisy. Pressure upon the artery by a tumor in the mediastinum, or by enlarged bronchial glands, may cause enough narrowing of its calibre to give rise to a murmur. In an article by R. Douglas Powell, in Reynolds's "System of Medicine,"⁸ a case is given where an aneurism of the aorta pressed upon the pulmonary artery, causing signs of pulmonary stenosis, as well as those of a thoracic aneurism. Displacement of the heart by fluid may also cause a pulmonic murmur. Hayden⁹ refers to cases reported by Da Costa, of pulmonic systolic murmur believed to be caused by the pressure of solidified lung on the left branch of the pulmonary artery. He also speaks of a case where such a murmur developed shortly before death, probably caused by thrombosis. None of the above conditions seem to exist in the case of Mrs. X. Her embarrassment of respiration dates back too many years, and has no history of any antecedent lung disease. One other cause of such a murmur needs only to be mentioned. In children, and in adults with thin, yielding chest walls, it may be produced by pressure with the stethoscope.

If then, this murmur is not inorganic, nor caused by pressure, or other causes outside of the artery itself, it must be caused by some obstruction within the vessel. This may be either a narrowing at the pulmonic orifice, some valvular lesion, or a diminution in calibre of the artery. Occasionally the stenosis takes place in the conus arteriosus, or infundibulum, of the right ventricle. Exactly what the condition is in a given case cannot be positively known. The general name of pulmonary stenosis embraces them all.

Such a lesion may be either congenital or acquired, with the probabilities very greatly in favor of the former. Rosenstein¹⁰ says that there are only a very

few scattered cases (he mentions four) of the acquired form, and on this point all authorities agree. In the *British Medical Journal* of a later date¹¹ is reported a case supposed to be acquired, and not congenital, and the specimen is described. It is usually the result of intra-uterine disease (endocarditis) or of arrested foetal development. A diagnosis between the acquired and congenital varieties in an adult cannot often be made with certainty. Keating and Edwards¹² say there is "no sign or sequence of signs by which a congenital murmur can be definitely differentiated from an acquired lesion." Bramwell¹³ says the history of the case is the only means of differential diagnosis, and we may be helped by the fact that several members of a family may have congenital heart disease. He also says it is "only when symptoms and signs of cardiac disease have been entirely absent in early life that the diagnosis of the acquired form can be made." On the other hand, even the history of cyanosis and dyspnoea from early childhood is not conclusive proof of congenital disease, as such a history may be found in other cases.

So that unless the case has been seen, both before and after the establishment of the murmur, the differential diagnosis seems to be purely a matter of probabilities. Assuming then, as there is no evidence to the contrary, that we have a case of congenital pulmonary stenosis, let us see what is the usual course of such a lesion, and then compare this with the history of the present case.

Of all forms of congenital heart disease, pulmonary stenosis is the most common. This stenosis may be at the infundibulum of the ventricle, at the pulmonary orifice, or a general narrowing of the artery and accompanied by different conditions of the various foetal openings, in the heart and great vessels. The most common form is stenosis of the artery itself, as far as its bifurcation. With this condition is usually found either an open foramen ovale, or a deficiency in the ventricular septum. The ductus arteriosus may be either open or closed, more often the latter. The interventricular septum is normally closed at the third month of foetal life. If the pulmonic obstruction occurs before this time the blood finds its way through this opening, preventing its closure. Obstruction occurring after the third month finds some relief by the flow of blood directly from auricle to auricle through the foramen ovale. After birth, in either case, some blood goes to the lungs through the ductus arteriosus, if this remains open. If this is closed there is a certain amount of collateral circulation established by means of the bronchial, oesophageal, or other branches of the aorta. Compensation for the stenosis is not perfect by any of these means, so that there is usually hypertrophy of the right side of the heart, with more or less dilatation, and also cyanosis and enlargement of superficial veins, in greater or less degree. The more complete the compensation, the less marked are the symptoms, or as Keating says, compensation is the "key-note in prognosis" in these cases.

Bramwell divides cases of stenosis into three groups, according to the severity of the symptoms.

(1) Where the lesions are severe, and the patients die at once or soon after birth. If they live for any length of time there is great cyanosis, a subnormal

temperature, somnolence, dyspnoea, dropsy, and often fatal convulsions.

(2) The lesions are less severe, and they may live several years, but with heart symptoms from the first. Cyanosis may be only noticeable on coughing or exertion, and is more marked on the periphery of the body. Fingers are clubbed, and superficial veins prominent. When compensation becomes imperfect, or is interfered with by intercurrent bronchitis or other trouble in the lungs, to which these patients are very liable, dyspnoea and palpitation increase. Oedema is usually a late symptom, at which period there may be convulsions. At the same time albuminuria and enlargement of the liver and spleen may be found. If the patients survive puberty, they generally die young from phthisis. Hæmoptysis is frequent, being often the earliest symptom of lung invasion.

(3) The lesions are slight, and symptoms may not arise till years after birth. They are caused by failure of compensation, which is either gradual, or brought about more rapidly by intercurrent disease. At about the time of puberty, compensation is very apt to be disturbed. The cases then run the same course as if the symptoms had been present from early life.

Children with this defect usually develop slowly, both mentally and physically. Menstruation is apt to be late in its establishment. The hypertrophied heart presses upon the yielding ribs and cartilages, causing a bulging of that part of the chest wall. A majority of the cases die before adult life is reached. The elements which favor survival are a slight or moderate degree of stenosis, a sufficient opening through some of the foetal passages, and a good collateral circulation. Lebert¹⁴ quotes a table from Kussmaul showing that out of 64 cases, 41 died under ten years of age, 14 between ten and twenty years, and only 9 lived beyond twenty years. One case of undoubtedly congenital stenosis lived to the age of sixty-five, and two cases of complete closure of the artery died respectively at twenty-one and thirty-seven years (Lebert). Another, with stenosis and open foramen ovale, died at fifty-seven, from cerebral apoplexy (Keating and Edwards, p. 38). These cases are, of course, exceptional. As a rule, even for favorable cases, middle age will not be passed, and there is a remarkable tendency for them to terminate in pulmonary tuberculosis, a combination which is rare in any other form of heart disease. This is a curious fact to which Lebert (in "Ziemssen's Cyclopædia") devotes considerable space. He finds that the cases so terminating show no hereditary tendency, and he can only ascribe this frequency of tuberculosis to a deficient blood-supply in the lungs, and the pressure upon them of an hypertrophied heart. The left lung is usually first attacked.

As no dyspnoea was noticed in the patient till she was ten or twelve years old, while it usually appears early, the following table (Keating and Edwards, p. 41) may be interesting. In 41 cases of congenital defect, cyanosis first appeared at the age of

2 weeks	in 3 cases
3 weeks	in 1 case
1 month	in 2 cases
1 to 2 months	in 7 cases
2 to 6 months	in 5 cases
6 to 12 months	in 5 cases
1 to 2 years	in 3 cases
2 to 5 years	in 6 cases
5 to 10 years	in 1 case
10 to 20 years	in 6 cases
20 to 40 years	in 1 case
Over 40 years	in 1 case

¹³ Loc. cit., p. 335.

In only nine did cyanosis first appear after the age of five years.

The case reported seems to be one of a mild degree of stenosis, and she has been able to live in great comparative comfort. She has been singularly free from any diseases tending to disturb the compensation effected by her moderately hypertrophied heart. There is evidence of some disturbance of compensation at about the time of puberty. She says she has had *la grippe* twice; but, if so, her account shows that neither attack could have been very severe. Cyanosis only shows itself in the extremities, and there has been no oedema except occasionally at the ankles. She has the cold hands and feet mentioned by the authorities. The physical signs about the heart and lungs support the diagnosis, though the cyanosis and dyspnoea, even on exertion, are of a milder degree than usual. Sansom,¹⁵ however, reports the autopsy of a child where pulmonary stenosis was found, though there had been absolutely no cyanosis, but rather pallor. The indications of hypertrophy of the right heart are less marked than usual, and there is not the epigastric impulse usually felt; yet this symptom was entirely absent in a case of congenital stenosis¹⁶ where great hypertrophy of the right ventricle was found, and where the symptoms came on suddenly at the age of eighteen. Her lesion is not severe enough to have interfered with her growth and development. As long as no extra strain is brought on her heart she is likely to go on as she is for some time. She has lived unusually long without the appearance of tuberculosis, which may be expected to develop later. It would not be surprising to see it show itself by hæmoptysis at any time, though at present her lungs seem to be in a normal condition.

The cause of cyanosis is an interesting question in this connection, which has been argued by several writers. Two theories have been advanced. According to one the coloration is due simply to venous stasis, the blood backing up in the right side of the heart, and then in the systemic veins. The other theory ascribes cyanosis to the fact that there is a mixture of unoxygenated blood circulating with the arterial blood, the two being allowed to mingle by the persistence of one or more of the foetal openings which should have closed under normal conditions. Some think the color of the surface is due to the operation of both of these causes combined. In an article on cyanosis in the *Practitioner* for 1888, the writer takes the ground that less than a normal amount of blood goes to the lungs in these cases. The lungs then become partially collapsed, respiration is impeded, and what blood does go to the lungs is not properly aerated. This he regards as one of the most important elements in producing cyanosis.

THE RADICAL CURE OF HYDROCELE.¹

BY M. F. GAVIN, M.D.

THE different methods used for the radical cure of hydrocele are antiseptic incision, excision of a part or the whole of the sac, and injection: all other methods are now obsolete. It is with the last-mentioned method my paper will mainly deal. The open inci-

¹ Read before the Boston Society for Medical Observation, January 1, 1894.

¹⁵ Lectures on the Physical Diagnosis of Diseases of the Heart, Philadelphia, 1876, p. 130.

¹⁶ Lancet, August 2, 1884, p. 183.

sion, with or without excision of the sac, means the administration of an anæsthetic, detention in bed for a varying period from one week to four, while to undergo an operation has considerable effect on the minds of most of our patients.

There are cases where the open incision is the only operation to be considered: where there is a question of diagnosis; where a hernia exists; where injection has failed—congenital hydrocele; where the sac is much thickened. In all of these some form of open operation is called for.

There is a large class that can be successfully treated by injection. Perhaps it is well to inquire why injection has so often failed to cure the disease.

Let us hear the explanation as given by Jacobson, for the many failures: (1) The use of too weak a solution; (2) not bringing the solution in contact with the whole of the sac; (3) not withdrawing all the hydrocele fluid; (4) injecting large hydroceles immediately after they are emptied; (5) making use of injections in unsuitable cases.

No simple, uncomplicated case of hydrocele ought to be treated other than by injection. The use of tincture of iodine, the simple as well as the compound, is too often followed by failure to urge its use, which is often attended by a scene—patients often fainting, and suffering from griping pains, retraction of the testicle, nausea and even vomiting; unpleasant things to have happen in one's office. Since about six years I have treated all suitable cases of hydrocele by injecting half an ounce of a solution composed of equal parts of carbolic acid, alcohol and glycerine—a small bulb syringe answers very well. A little care is necessary in the use of the solution. Protect the skin surrounding the canula with a little gauze or absorbent cotton, so as to avoid the burning sensation so easily produced on the tender skin covering the scrotum; allow the fluid to remain. The injection is practically painless, and no unpleasant effects follow its use. Patients are allowed to attend to their ordinary business; and in from two to four weeks the acute hydrocele disappears.

I have no record of the number of the cases so treated; but since I have used it, I have seen only one relapse. The method has proved so effective, and with none of the drawbacks of other methods, that I feel warranted in bringing it before the Society. I have never dared to use carbolic acid as recommended by Dr. Levis. I am unable to give the name of the originator.

Medical Progress.

RECENT PROGRESS IN OBSTETRICS.

BY EDWARD REYNOLDS, M.D.

SINGLE LIGATURE OF THE CORD.

NGUYEN KHAC CAN¹ bases his opinion of the superiority of a single ligature upon his observation that out of 68 cases of labor with double ligature of the cord, there were four cases of retention of the placenta; and out of 146 cases with single ligature, only two cases of retention. The duration of the third stage with the double ligature averaged 64 minutes, while with the single it was but 27 minutes.

¹ Algeria. Arch. de Toe. et de Gyn.

The author believes that a rapid diminution in the size of the placenta, due to the free escape of the intra-placental blood, favors retro-placental hæmorrhage, and consequent complete separation of the placenta, and that it further lessens the obstacle to its escape from the uterus and vagina by the resulting decrease in size. He recommends that double ligature of the cord should be reserved for cases of twin pregnancy. While we think that there is a question as to the correctness of the author's reasoning on the first point, there can be no doubt as to the advantage of diminishing the size of any body which is to pass the os uteri, and we think that we have ourselves noticed a greater ease of delivery of the placenta in cases in which but one ligature had been applied.

The suggestion of Nguyen Khac Can is certainly of value. It should be easy to prevent untidiness by catching all the intra-placental blood in a suitable basin, but the determination not to check intra-placental hæmorrhage, of course, implies a careful palpation of the uterus before the cord is cut, and an absolutely positive elimination of the possibility of a twin pregnancy.

CHOLERA IN PREGNANCY AND LACTATION.

L. Gaillard² reports seven cases of cholera during pregnancy. Five terminated fatally, two were lightly attacked and recovered. The synopsis of the fatal cases is as follows:

(1) Seven months pregnant; premature labor on second day; intravenous transfusion. Patient died on the sixth day.

(2) Eight months pregnant. Labor did not appear. Death of the fœtus on the sixth day, and of the mother on the eighth day.

(3) Six months pregnant. Intravenous transfusion on the fourth day. No labor. Death of fœtus on the seventh day; of the mother on the tenth day.

(4) Patient tuberculous, and six months pregnant. Death of the fœtus on the ninth day; of the mother on the fourteenth. No labor.

(5) Eight months pregnant. Fœtus dead when first seen. Spontaneous labor on the eleventh day. Intravenous transfusion just before death.

Gaillard thinks that four of these cases would have recovered, if they had not been pregnant. His experience supports the classic belief that pregnant women support cholera badly; that the disease is almost invariably fatal to the fœtus; that it is almost always accompanied by abortion, miscarriage, or premature labor; that such an occurrence increases the danger to the mother; and that this risk increases in proportion to the previous duration of labor. Gaillard has seen nearly 400 cases of cholera, and considers pregnancy by far the most serious complication of the disease, worse even than senility and phthisis.

When nursing women are attacked by cholera the mammary glands frequently become congested and painful. In spite of the depleting effect of choleraic diarrhœa upon all the other fluids of the body, the secretion of milk persists in normal quantity. Lactation does not seem to be a serious complication, so far as can be judged from the author's experience, six out of ten patients having recovered.

SYMPHYSEOTOMY.

The proper limitation of the field for this operation,

² Arch. de Toc. et de Gyn.

the determination of its value and of its risks, have occupied a prominent place in the obstetrical work of the past six months; as is evidenced by the publication of 64 papers upon the subject during this time and of about half that number of cases.

Byron Stanton² gives a good abstract of the latest opinions of the best authorities upon the amount by which the pelvic space is increased.

Experiments upon puerperal cadavera have shown that the gain in the pelvic diameters is in direct proportion to the amount of separation; that, in high degrees of contraction, the proportional gain is greater than in normal pelves and in the lower degrees of deformity; that this gain is not limited to the conjugata vera, but is also present, and to a greater degree, in the transverse and oblique diameters, at both the inlet and outlet; that the increase of these latter diameters varies between three-fourths and one-third of the length of the inter-pubic separation, while the increase in the conjugata is about one-fourth of this space. Morisani quotes experiments showing that for each centimetre of pubic separation, the lines between the promontory and the extremities of the separated pubic bones are increased two and one-half millimetres, that is, that two inches of separation of the symphysis would yield a gain of half an inch in the conjugata; while with three inches of separation, the gain is three-fourths of an inch; and to this amount is added a possible still further gain by the projection of one parietal protuberance into the distensible space between the separated pubic bones. Cases have been reported in which more than three inches of separation has been possible without injury (Novi, of Naples, $3\frac{1}{2}$ inches; Caruso, $3\frac{1}{2}$ inches); but, as a rule, three inches is the extreme degree of separation which is safe. We must not, therefore, count upon a gain of more than three-quarters of an inch in the conjugata, an inch in the oblique, and an inch and a half in the transverse diameters.

Limitations of the Operation.—The size of pelvis in which symphyseotomy is appropriate has been placed as low as $2\frac{1}{2}$ inches, and as high as a normal pelvis with an unusually large head, but these limits are probably far too wide. At the lower limit given the operation would probably result in the loss of the child unless the latter was extremely small. The application of this operation to normal pelves can hardly be too severely criticised. It is probable that there is not one case in 10,000 in which, in competent hands, the loss of the child during its extraction through a normal pelvis can fairly be laid to pure disproportion between the head and pelvis, and the success of symphysiotomy has been so marked that there is grave danger that it may be used in cases that could be treated equally well by the ordinary obstetric operations.

Technique.—The most scrupulous asepsis is necessary. The first step in the operation is freeing the surface of the mons veneri and labia majora of hair, rendering the skin thoroughly aseptic by the usual methods of preparing the abdominal walls for cœliotomy, and disinfecting the vulva and vagina. The patient may be placed at the side of the bed with knees drawn up and separated, or the operator may take his place between the extremities of the patient.

The technique of the operation has been improved by the more complete separation of the operation wound from the vulva by making the division of the symphysis subcutaneous. The incision should lie in

² Am. Jour. Obst., September 1896.

the median line, should be long enough to admit two fingers, and should terminate at its lower extremity just above the symphysis. This incision not only renders asepsis more easy of attainment, but places the wound in a situation where the bandage which fixes the pelvis during the after-treatment does not press upon the wound. The incision should be carried through the skin and subcutaneous fascia, and should lay bare the insertions of the recti on the pubes. These should be separated from the pubic bones by a transverse subcutaneous incision to an extent sufficient to admit two fingers, and care should be taken that the prevesical space is not opened in separating these insertions from the bone; as the posterior layers of the fascia of the abdominal wall may with care be separated from the symphysis by blunt dissection with the finger without this accident. A catheter should be passed into the urethra, and the soft tissues behind the symphysis widely separated from the bone by the finger. It should then be placed behind the symphysis with its tip upon the subpubic ligament; Galbiati's knife, Harris's modification of the same instrument, or in case of emergency any strong blunt-pointed bistoury, should be passed behind the symphysis with the finger as a guide, and should divide the joint and subpubic ligament from behind forwards, and from below upwards. The operator should then open the symphysis by abduction of the patient's knees, and should continue the separation till he judges that a sufficient amount of space has been gained, or till he feels the check due to the sacro-iliac ligament. The wound should then be covered with a protective dressing and a firm bandage placed around the pelvis below the crests of the ilia in such a manner as to prevent any further separation during the extraction of the child. After the delivery of the child the bladder should be injected with warm milk or some bland, colored fluid in order to determine the existence of any injury which may have been inflicted upon this organ during the extraction. Should such be found, it should be repaired at once. If no injury is detected, a strip of gauze should be placed in the wound, the remainder of the skin wound should be sutured; a dressing should be applied; and the divided surface of the symphysis should be held in place by a firm bandage round the pelvis below the crests of the ilia.

Mortality.—The latest general statistics noted gave a death-rate of about six per cent. from all causes; but it must be added that in many of the cases the patients were already in bad condition, and that the fatal result could be attributed to the operation itself in only one case (to be referred to later). These statistics are incomplete, contain the early cases, and are probably less favorable than could be now reported, unless an allowance must now be made for the fact that fatal cases are often unreported. Dr. R. P. Harris, in a recent personal letter, says that there have been 35 American cases, with four deaths. Of these, one was due to post-partum hæmorrhage, *unconnected with the operation*; one was due to shock in a much exhausted patient, *more the result of neglected labor than of the operation*; one was due to uterine sepsis, the operative wound remaining clean, *probably unconnected with the operation*; and one was due to sepsis in the symphysectomy wound, *directly a result of the operation*. Among the successful cases there had been no permanent unfavorable after-results. The operation must then be still considered a major procedure with a considerable mortality; but it is only fair to add that

among the cases which were operated upon early, there has so far been no death-rate peculiar to the operation, other than that from sepsis, which should, of course, be preventable.

ECLAMPSIA.

Alphonse Hergott⁴ has conducted a further series of experiments with the blood and urine of women suffering from eclampsia. His investigations lead him to believe that the convulsions of parturient women may be produced by either of two different causes. The first class he considers due to lesions of the kidneys; and the renal lesion may, he thinks, be produced by pregnancy. The second variety of eclampsia he considers due to the activity of a special pathogenic microbe which finds a suitable field for its development only when the organism has been modified by pregnancy. The first is an auto-intoxication, the second a bacterio-intoxication. He thinks it likely, though not yet proved, that eclampsia of the second variety is not caused directly by this microbe, but by the action of the toxic products of its activity upon the nervous system, when modified by pregnancy.

A. Charpentier⁵ writes upon the treatment of eclampsia from the basis of a clinical experience, which he has divided into three classes: The first treated by blood letting; the second with sedatives, that is, chloroform or chloral; and the third by the prompt termination of labor. He is an advocate of active interference when labor is already underway, but refuses to induce labor unless in very exceptional cases. He bases this refusal upon the following theoretical considerations: He believes emptying the uterus may ameliorate the condition of albuminuria and eclampsia, but cannot cure it, as it depends on a renal lesion, which may not disappear with the delivery of the child; the induction of labor requires a longer time than is consumed in an eclamptic attack; any excitation of the uterus is sufficient to cause a convulsion; the manœuvres necessary to the induction of labor necessarily furnish such excitation. He mentions forced labor only to condemn it. He recommends the administration of chloral by enema in doses of one drachm of the drug every five or six hours, and uses chloroform at the time of each seizure, advising conservative treatment till labor appears. If labor is fairly rapid, he deprecates interference, but, in case of delay, permits the use of forceps.

Charpentier believes that venesection may be of value in cases where congestive symptoms are permanent, and especially where there is reason to believe in the existence of congestion of the lungs or brain. He thinks that, though not in itself a cure, it can be counted upon to diminish the frequency and force of the eclamptic seizures. His conclusions are as follows:

(1) Whenever a trace of albumen is found in the urine of a pregnant woman, she should be put at once on a rigid milk diet.

(2) When the convulsion occurs in a strong woman of full habit and is accompanied by marked cyanosis, bleed and administer chloral as described.

(3) If the patient is delicate and the cyanosis is not extreme, the treatment should be limited to the use of chloral.

(4) Let labor appear spontaneously, and be concluded by the efforts of nature whenever this is possible.

⁴ Annales de Gynecologie.

⁵ Nouvelle Arch. d'Obst. et de Gyn.

(5) Should interference be necessary, deliver as rapidly and with as little manipulation of the uterus as possible.

(6) Interference should never be resorted to till the os is fully dilated.

(7) Labor should be induced only in the very exceptional cases, in which all other methods fail to check the attacks.

(8) Never resort to forced labor.

One is struck by his entire neglect of the active treatment of the skin and kidneys, upon which American obstetricians have been accustomed to place the first reliance; and we cannot but believe that his objection to forced labor, that is, gentle but rapid dilatation of the os and subsequent immediate extraction of the child, under full surgical anæsthesia, is due to the fact that he has reserved it for desperate cases, and for them only, instead of resorting to it, as is the practice here, whenever the convulsions are so frequent and severe as to make the prognosis for the mother really grave, or whenever in milder cases the patient's condition fails to improve under conservative methods.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

JOHN C. MUNRO, M.D., SECRETARY.

REGULAR meeting, Monday, January 1, 1894, DR. J. STEDMAN in the chair.

DR. M. F. GAVIN read a paper on

THE RADICAL CURE OF HYDROCELE.¹

DR. GAY: I have used the pure carbolic acid treatment in three cases, and it is a pretty severe treatment and not a very certain one; so I long ago gave that up. At one time the red oxide of mercury was talked about. It consisted in tapping the hydrocele, and then with a small director or grooved probe carrying a little of the oxide into the sac. It seemed to me a bungling way. Then I learned the method I think a good deal of, and that is tapping, emptying thoroughly and injecting two ounces of the compound tincture of iodine. The compound tincture is especially indicated, because that mixes thoroughly with water or with this fluid of the hydrocele. It is squeezed about inside of the sac, so that all parts shall be bathed with it, and then all that will is allowed to run out of the canula. I have used this treatment a few times in my office, and so far I like it. I never have had but one uncomfortable result from it, and that was a spasmodic retraction of the testicle. This in one case was rather uncomfortable for two or three weeks, but it finally passed away, and the man got a complete cure of his hydrocele. The only points about it are, that the sac is to be thoroughly emptied, the compound tincture to be used, and enough used to thoroughly moisten the inside of the sac, and then the superfluous part to be allowed to run out. The pain for two or three minutes is intense, and then it gradually quiets down, so that by the time the patient leaves the office he has a feeling of warmth in the scrotum. I do not claim this as a universal cure; but, aside from the pain, it is a very good way of treat-

ing the hydrocele that are not too old. I think Dr. Gavin's classification is an excellent one. The old ones want something more than injection.

DR. BURRELL: I was not fortunate enough to hear Dr. Gavin's paper. There is one point about the question of radical cure for hydrocele of which I should like to speak. Of late I have been making open incisions and packing the sac of a hydrocele. I have been strengthened in my opinion that this was the wisest procedure by what I have found inside the sacs. Not infrequently I have found bits of fibrinous material which acted as foreign bodies, which were a constant source of irritation, and which kept up the effusion of fluid into the tunica vaginalis. This has led me to lean strongly towards the more radical operation of opening and seeing the condition inside the sac than to the more indefinite method of injection.

DR. RICHARDSON: I am sorry I was not able to hear Dr. Gavin's paper. I have preferred when possible to dissect out the sac entirely. My experience with milder methods, like injections of iodine and carbolic acid, is very limited. I have seen all methods fail except the dissection and removal of the sac. This is surely the end of the hydrocele, but in many instances the method is severe. With a patient unwilling to submit to so radical a measure I have always intended to use the method of injection. Such methods are very desirable in those cases in which for any reason it is unsafe to etherize or to subject the patient even to the slight dangers of radical excision of the tunica vaginalis.

DR. GAVIN: I should like to ask Dr. Richardson if he had a simple case of hydrocele come to his office, who had not been tapped, if he would recommend excision without any treatment to begin with?

DR. RICHARDSON: If the patient wishes to be absolutely certain of cure, and if there is no reason against the operation, the best plan is to dissect out the whole tunica vaginalis except the portion that covers the testicle. I prefer this method because I am used to it, and it is always successful. The operation should be limited to simple drainage when the sac is very thick and adherent. In children I make a simple puncture of the sac with a glover's needle,—a method which sometimes succeeds and sometimes does not.

I do not wish to be understood as opposing the method recommended by Dr. Gavin, for I have had no experience with it. I have no doubt that his method will be found admirable in a great variety of cases. Now and then, however, one will be found in which the fluid will return. This recurrence is seen in all operations upon hydrocele except that of complete extirpation of the tunic. In one instance I found a hydrocele of the cord which pressed upon a hydrocele of the tunica vaginalis, the two being blended into one tumor; this accounted for the return of the hydrocele. The second attack was a hydrocele of the cord.

Perhaps I am too much inclined to give the patient the more radical operation first, for there is certainly no objection to trying the methods which may be called palliative. The last radical operation that Dr. Mumford and I performed was about two weeks ago upon a man of seventy. I had tapped him for a long time, and advised him to continue that treatment. He decided, however, to have a radical cure. We removed the tunica vaginalis entirely, and he has made a most satisfactory recovery.

¹ See page 210 of the Journal.

DR. G. W. GAY read a paper on

MALIGNANT DISEASE OF THE RECTUM.*

DR. BURRELL: I have been very much interested in the paper presented by Dr. Gay. Recently I have twice supposed that I was going to operate upon a case of hemorrhoids, and a careful rectal examination under ether showed the presence of malignant disease high up in the rectum; and I believe that a high rectal examination cannot be too strongly insisted upon before any operation about the sphincters is undertaken.

In reference to Dr. Gay's position in regard to the radical cure of cancer in the rectum, I am very much disappointed at his outlook. I have been looking at the operation for the relief of cancer in the rectum in a much more favorable light. After listening to the report of his cases, especially the one in which after four years the disease returned, I shall be very loath to speak of any permanent cure of a case under four years. Before I heard Dr. Gay's paper I had arranged the operations for cancer in my mind in this way: Excision of the growth in the lower end of the rectum, and a Kraske operation for excision of the growth in the upper part of the rectum. I have come to believe that an iliac colotomy is the operation of selection as a palliative measure. It is simple; the relief is very great; and it has seemed to me a preferable operation to lumbar colotomy, which requires a deep dissection; and the location of the two openings is in favor of the iliac operation, as an artificial anus in this position can be better controlled. In favor of the Kraske operation, I can say that I have one patient upon whom I operated two years ago, and whom I have seen within a month, where there has been no return of the disease. I shall evidently have to wait longer before claiming a permanent cure.

But setting aside for a moment the question of its being a radical cure, I think there is a word to be said in reference to the Kraske operation as a palliative operation. On comparing it with lumbar colotomy and iliac colotomy, an iliac colotomy simply taps the stream of feces above the disease, and leaves the growth *in situ*; and while occasionally it is possible to make a spur in the bowel which shall prevent feces passing beyond the artificial anus, yet this is often unsuccessful. This has always seemed to me an objection to colotomy, in that it does not deal with the disease *in situ*. On the other hand, the Kraske operation, as I have recently performed it, does not seem to me as severe as it sounds in description. To speak of the removal of the coccyx and the removal of a portion of the sacrum, seems a great deal, as we listen to it; but if carefully and rapidly performed, and especially if, after removal of the coccyx and a portion of the sacrum, one cuts into the right cellular interspace and practically shells out the rectum by a "dry dissection," there is but very little bleeding. On clamping the rectum above the growth and below, a quick excision of it can be made; and even if the peritoneal cavity is opened, it can be sutured, and but little danger exists of infection, especially if the patient is kept in a semi-upright position.

By the Kraske operation we have all the benefit of a colotomy, plus the great relief of the complete removal of a mass of malignant disease, which, of course, may return in the future. Patients after a Kraske operation are very comfortable, have but little pain,

and when a pad is properly adjusted can go around with but little inconvenience to themselves and no offensiveness to others.

DR. J. C. STEDMAN: During my service on the house-staff of the Post-Graduate Hospital, New York City, I find, on looking over my records, in the service of Prof. Charles B. Kelsey, 14 cases of malignant disease of the rectum treated by him; and of these, 10 were treated by inguinal colotomy, two by extirpation (Cripps's method and Kraske's method), one by inguinal colotomy first and subsequently amputation of rectum, and one was discharged without an operation. Twelve of these cases were discharged very much relieved and improved; and two died in the hospital. As most cases of malignant disease of the rectum consult the surgeon three or four months after they complain of the first symptoms, it only remains for the surgeon to give them some form of temporary relief, for in these cases they will generally suffer a great deal before they will make up their minds to accept the treatment proposed by the surgeon. Therefore it is according to the extent of the disease and the severity of the symptoms that will determine the line of treatment to be carried out, whether simply palliative or more radical. As most of the cases of cancer of the rectum treated by Professor Kelsey in the Post-Graduate Hospital were those where the disease was advanced three months or more, and not only the rectal walls, but the surrounding tissues were involved, he therefore performed inguinal colotomy on most of them, as the best plan of treatment for the immediate relief of distressing symptoms and also prolongation of life. If the bowel is diseased within three inches of the anus, and from examination it is thought to involve only the gut, then Professor Kelsey may perform Cripps's operation, or proctotomy; and if the disease is above that and below the promontory of the sacrum, and the gut only involved, then he may perform Kraske's operation, or else amputation of the rectum; but generally he prefers inguinal colotomy, and presently I will give his reasons for the same.

I will not take the time to review the 14 cases in detail, but only to state, in general, that most of them were suffering with burning sensation in the rectum; great pain on going to stool, with frequent desire and great tenesmus, and passing large quantities of blood and mucus; losing flesh and strength; having in some cases fulness over the abdomen; not able to sleep well at night, but constantly getting up to use the commode, and suffering great pain. Of course, these cases were in various stages of development, generally three months to a year from the time they noticed the first symptom, and located in different parts of the rectum, and in one case in the sigmoid flexure.

Professor Kelsey prefers inguinal to lumbar colotomy for several reasons: It is an easier and quicker operation, and as safe if not safer in these days of antiseptic surgery. Another great point in its favor is the convenience to the patient in keeping the parts clean, as compared with the difficulty and inconvenience of doing the same in the lumbar region; and the terminal portion of the gut can be more easily cleaned out of any fecal or irritating matter which may collect in it.

The technique of the operation, as performed by Professor Kelsey, has been admirably described by Dr. Gay. I will simply lay more emphasis on the silver wire which forms the spur, as Dr. Kelsey is very particular in regard to forming a good spur in the

* See page 204 of the Journal.

bowel. The silver wire is passed an inch from the right of the line of incision, and half-way between the middle and lower thirds of the incision, through the muscular walls, peritoneum, under the gut, through the mesentery, and up the opposite side an inch to the left of the incision, and then drawn tight and fastened with the lead button and slot. It thus forms an excellent spur, and when opened serves as a barrier to the feces from passing down the terminal end of the bowel. The colon is left intact for two days, unless for some counter-indication, in order to allow the peritoneum time to adhere firmly to the colon, and thus prevent extravasation of feces into the abdominal cavity. It is then opened with a curved bistoury and scissors, cutting well down to the line of incision, no ether being necessary. From that time on, the patient, as a rule, will have one to three normal movements a day. The wire is taken out at the end of the fourth day, and the patient is generally sitting up at the end of the tenth day.

The wound, immediately after the operation, is dressed; first, with Lister's protective next to the bowel and incision, to prevent the parts and dressings from becoming matted together by the effusion of lymph; next to that, bichloride pad and gauze, cotton and bandage. After the gut is opened, a simple dressing of sheet-lint, vaseline, cotton pad and bandage is all that is used. At the end of the third or fourth day the distal end of the bowel is generally irrigated with a weak solution of carbolic or bichloride, or even hot water—either from anal opening or the inguinal. When the patients leave the hospital they either use one of Dr. Kelsey's trusses, made for the purpose, or the pad and bandage mentioned above.

Professor Kelsey's reasons for preferring inguinal colotomy are these, as he has stated to the class over and over again; they will be found in the fourth edition of his works on rectal diseases:

"It prolongs life by the relief of pain. It substitutes in many cases a painless death for one of great agony; . . . does away with the constant tenesmus and discharge from the rectum, which by their exhausting effects are the immediate cause of death; delays the development of the disease by preventing the straining and congestion of defecation; prevents absolutely the complication of intestinal obstruction, which is another cause of death; enables the patient to sleep, eat and gain flesh; and often makes him think himself cured in spite of the plainest prognosis to the contrary. Instead of passing his days and nights upon the commode, wearing out his life in the effort to free the bowel from its irritation, he has one or perhaps two solid fecal evacuations from the groin in twenty-four hours. Is it pleasant to have the gut end in the left groin? No. But after a very few days the patient with cancer of the rectum, whose anus has been placed in the groin by the surgeon, will tell you that life, from having been a constant torment, has again become worth living."

Another reason is, the mortality is less in inguinal colotomy than in any other operation for malignant disease of the rectum. During my service with Professor Kelsey, he performed 16 inguinal colotomies:

10 were for malignant disease of the rectum.

2 were for non-malignant stricture.

1, ulceration, with stricture.

1, extensive dysenteric ulceration.

1, dysenteric stricture.

1, stricture of sigmoid flexure from pelvic cellulitis, with abscess.

Of these 16 cases, two died; the others were discharged much relieved and improved.

I speak of these for this reason; it is thought by many physicians, and very naturally so, of course, that it is very disgusting to have an anal opening in the groin and that patients object to it very much. Now my experience in the hospital has been the reverse of what would be supposed. Over and over again, the patients have said, in person or by letter, that "they would not return to the old order of things—pain, tenesmus, blood, etc.—on any account"; that they were perfectly satisfied and very much pleased with the relief obtained. And of the lesser evil, inguinal colotomy is to be preferred; and in most cases they have gained strength and flesh.

Therefore, the good results obtained, as regards quickness of operation, relief of distressing symptoms to patient, and prolongation of life, makes inguinal colotomy the line of treatment preferred by Prof. Charles B. Kelsey in the great majority of cases of malignant diseases of the rectum.

DR. M. H. RICHARDSON: I am very much interested in the practical aspects of this paper. We owe a great deal to the older men who call our attention to the results of their experience in diseases of this kind. As our experience gets larger, and after we have seen so many recurrences following operations for cancer, we cannot but become more and more conservative in advising surgical interference. Some years ago I looked up the ultimate results of all the operations performed upon cancer at the Massachusetts General Hospital for ten years. The results in breast cases were encouraging, especially after the radical operations performed in the later years. Cancer of the tongue was invariably fatal sooner or later. I did not investigate cancer of the rectum; I took it for granted that the patients were all dead. At the present time, nevertheless, I do not feel as hopeless in regard to malignant disease of the rectum as Dr. Gay does. In the first place, we must be very careful that our examination is thorough in cases of suspected cancer of the rectum. If we examine thoroughly every case of suspected cancer, and take nothing for granted, we discover frequently facts of the greatest importance, and at times avoid errors in diagnosis that would be laughable if they were not tragic. I remember a case that came to me with a diagnosis of cancer of the rectum—a hopeless case. On careful examination I found a carious coccyx surrounded by inflamed and thickened tissues quite like cancer on careless examination. I removed the dead bone and the man recovered. In connection with the difficulties of diagnosis at times, I would like to speak of a man operated on in one of the New York hospitals, for malignant tumor of the bladder. He recovered perfectly from a very brilliant operation. Later I examined him, and told his friends that he could not live. There was a long scar in the linea alba, in the mass of an evidently recurrent malignant tumor. He had a hopeless recurrence, as I thought; but I heard the other day that he got perfectly well, and is now at work in perfect health. This was a mistake in diagnosis, even after the greatest care in examination, in operation, and in gross inspection of the tumor: followed by the most expert microscopical examination. We ought, nevertheless, to have a microscopic examination in every case.

The only favorable instance of removal of malignant disease of the rectum in my practice was that of

a jeweller who had to sit all day on a high stool, and who noticed very early some trouble in his rectum, which I supposed to be cancer. I operated on him three or four years ago; a year later I repeated the operation for a recurrence, though I had no idea that the man would permanently recover. Yet he has been well ever since. Presenting at first the general and local characteristics of malignant disease, he now has become robust, and there is no local recurrence. But the disease was not cancer; it was a malignant adenoma, with infiltration and induration. The pathologists have told me that in the cases of malignant adenoma, if we can get the disease all out, the prognosis is very good. While operating, we should have always at our elbow the microscopist, as we should have in abdominal work the bacteriologist.

In regard to the Kraske operation and its modifications, I have seen this operation performed, but I have never found a case of my own in which it seemed best to perform it. The mortality is 28 per cent., as recently reported by Kraske, and by Schide 35 per cent. — somewhat higher than Kelsey's.

I have performed many times the operation of inguinal colotomy, but I have never felt obliged to make a spur. Almost always the operation has been performed for cancer of the sigmoid flexure. I have operated in the left groin, right groin, and median line for the disease. For cancer of the rectum colotomy has been done very infrequently in my practice. I have never seen any subsequent distress or discomfort from the absence of a spur, though I dare say that this is completely at variance with the experience of others. In one instance I opened in the left and found a distended coil of intestine, fastened it to the groin, and opened immediately. The opening proved to be in the head of the cæcum. The patient lived about a year in a state of comparative comfort, resumed his duties in college, gave his lectures, and told me the year had been a year of satisfaction and happiness. I do not say that it is not a good plan to make a spur such as Dr. Kelsey has described, or one like that which Dr. Keene has just reported, but I have not seen any good reason for following the method in my own cases. I dare say that it is better in some instances to provide for the total escape of the contents through that opening, but not infrequently strictured bowel becomes pervious. In several cases the artificial anus has closed entirely, the discharges have resumed their normal course, and the patient has been relieved from the discomforts of the artificial opening. Under these circumstances the local discomfort from obstruction and from tenesmus has also disappeared.

It is said in cancer of the rectum, as in cancer of the breast, that three years of immunity after operation means cure. I do not believe in this time limit — at least not enough to feel safe as to recurrence even after five or six years. Absence of recurrence after operation on the breast at the end of three years is no certain assurance that the patient is safe. Those who have watched the progress of enlarged axillary glands when only the breast has been removed, must have observed how slowly at times they grow. In certain instances it has taken two or three years before they could be very perceptibly felt; yet, of course, the cells of the disease have been there and have been proliferating. I do not believe, therefore, that we can adopt any such limit as three years, and say that if the disease returns before three years it is not a cure, while

if it returns after three years it is a second and wholly distinct attack. In looking up a very large number of cases of breast-cancers there were many instances in which after four, five, or six years the disease had not returned; on the other hand, there were one or two cases in which after four or five years there was a recurrence. In cancer generally, therefore, I do not feel sure that the patient is permanently cured until many years have elapsed without a sign of reappearance.

DR. GAVIN: My experience for relief in malignant disease of the rectum has been wholly confined to colotomy. I have always done the lumbar colotomy. I have done that operation eight or ten times. I have never had any difficulty about the absence of the spur. I had one case at the City Hospital two and one-half years ago. A man had complete obstruction of the bowel. I did the lumbar colotomy. He went out well and engaged in his ordinary occupation, and a year and a half later he came to my office to know if he could not have that thing sewed up. A few months later he died. Lumbar colotomy has always given relief to the patient, and I have no doubt prolonged the life of the patient.

DR. PAUL THORNDIKE: I want to say a few words about the Kraske operation, as compared with the anal operation of Mr. Cripps. While it is true that we are not justified to-day in promising our patient a cure from either of these operations, it is also true that both have distinct and well-defined places in surgery. In cases when the disease is low down near the anus we do the Cripps operation, hoping for a radical cure, and sure that if our patient survives we shall have prolonged his life and lessened his pain. For these same reasons should we make use of the Kraske operation in cases when the disease is higher up in the rectum. The former operation has a mortality of 10 to 15 per cent., is bloody and inaccurate. The latter operation has a slightly higher mortality — 15 to 20 per cent. — is less bloody, and offers an easy, direct road to the diseased bowel, thus making possible a very careful and thorough removal of the diseased area. It is an operation which seems more severe than it really is, and which is not receiving the attention it deserves in this country. Whatever may be our belief as to the possibility of radical cures of rectal cancer, there is a certain percentage of cases when the disease is apparently well defined and limited to the anal region, where it is plainly our duty to try for a radical removal of the disease. Just so there are other cases when the disease is higher up in the bowel, where the Kraske operation is demanded.

DR. RICHARDSON: I hope that my remarks will not be understood by Dr. Thorndike as opposing this operation. I did not intend to oppose it, because I have seen it most successfully used in the hands of Dr. Cabot; moreover, it seems to me at times a most desirable procedure. I spoke of the dangers from having seen Schede's and Kraske's mortality recently reported — one of 28 per cent. and the other 35 per cent.

I have demonstrated the anatomy of this operation time and again at the school; it is a beautiful way of getting at the rectum. I have not performed the operation because I have not seen a case in which it seemed wise to apply it. In the hands even of an experienced operator it is one of the bloodiest operations I have ever seen. I remember one of the first cases at the hospital; the hæmorrhage was so great that we had no

idea that the patient would live; but she did live, and a very satisfactory result followed. I was surprised to hear Dr. Thorndike say this is a palliative method. I had supposed it was intended to be the most radical of radical measures.

I have seen recently described a method of bringing the upper part of the bowel down into the lower, so as to prevent formation of fistula and to restore the function of the bowel. If this could be performed successfully, we should have a most desirable condition of things, — the absence of opening in the groin and re-rotation of the alimentary canal; yet it seems to me that the dangers are great, and that they must be great until we have had considerable experience in performing the operation.

In regard to the difference between the lumbar and inguinal colotomy, I should like to see Dr. Gavin a convert to the inguinal method. I abandoned entirely the lumbar route, after having performed the Littré operation a few times. The advantages of the latter method are so great, both as to *technique*, and as regards the subsequent ease of the opening, that it seems to me very certain that lumbar colotomy will be performed only in those cases of obstructive cancer which are situated too high up for the inguinal incision.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING.

A STATED meeting was held at the Medical Library, Boston, on Wednesday, February 7, 1894.

The meeting was called to order at eleven A. M. by the President, DR. JAMES C. WHITE. One hundred and nine Councillors were present.

APPOINTMENT OF DELEGATES AND COMMITTEES.

On nomination by the Chair, the following delegates to other State medical societies were appointed:

Maine: Drs. J. E. Garland, of Gloucester; M. H. Richardson, of Boston.

New Hampshire: Drs. J. G. Blake, of Boston; C. C. Odlin, of Melrose.

Rhode Island: Drs. F. W. Goss, of Roxbury; R. H. Faunce, of Sandwich.

Connecticut: Drs. G. E. Francis, of Worcester; C. H. Cook, of Natick.

New Jersey: Drs. C. A. Carlton, of Salem; H. Colt, of Pittsfield.

Committees were appointed:

To Audit the Treasurer's Accounts: Drs. G. G. Tarbell, A. D. Sinclair.

To Examine the By-Laws of District Societies: Drs. S. D. Presbrey, F. W. Chapin, H. J. Barnes.

In accordance with the recommendation of the Committee on Medical Diplomas, it was voted that the degree of Tufts College Medical School be recognized by the Society.

The principal interest in the meeting centred about the report of the Committee on Securing Uniformity in Censors' Examinations. The President, as Chairman of the Committee, offered the report, and made remarks in support of the statements in the preamble. The report was as follows:

At a meeting of the Councillors, held October 2, 1893, the report of the Committee on securing Uniformity in

Censors' Examinations was presented. To it objection was raised that it might exceed the limitations of the charter. The subject was thereupon referred to a new Committee, to be appointed by the Chair, and to include the President himself. The Committee thus appointed, consists of one member from each District Society.

Your Committee has carefully considered many plans for the establishment of a uniform examination of candidates for admission to this Society. The present status for admission is somewhat as follows: Different standards are established by eighteen different Boards of Censors, not acting in concert, and having only in common the welfare of the Society. The objections to this plan are the following:

(1) That in certain Districts a comparatively severe examination is held for admission to the Society; that in other Districts a comparatively easy examination is held.

(2) That the Boards of Censors, as a rule, are composed of young men but a few years out from the Medical School, who are naturally sharper critics than the older Fellows of the Society.

(3) That at present the Boards of Censors know very little of the requirements for admission into other State Societies.

(4) That there are many excellent regular practitioners scattered throughout the State, and that their number of late has been increasing, who are not members of the Society. This is owing to failure on their part to present themselves for admission to the Society, and this failure is due to their wishing to avoid the rigor of an examination conducted by young men; in many instances by rival practitioners.

We believe that it will be for the interest of the Society to establish a uniform standard of examinations throughout the Commonwealth, and further that such examinations shall be elastic at the discretion of the Censors, in order that practitioners of established reputation shall not be hindered from entering the Society.

In order to accomplish this object your Committee respectfully suggests that the Councillors and the Society authorize the following changes in the By-Laws.

(1) By-Law I to be changed by striking out part of line 21 on page 9, and lines 22 to 26 inclusive, and substituting the following words, so that the By-Law shall read, "and, by such further examination as the Censors shall deem expedient."

(2) By-Law XIII to be changed by omitting the words "five Censors," in line 22, and adding in line 23 the words "five Censors, all of whom shall have been Fellows of the State Society for at least ten years, one of whom shall be also a Councillor, and be designated a Supervisor, and Ex-Officio Chairman of the Board of Censors."

(3) By-Law XIX to be changed by adding after the word "held," in line 19, the words "they shall appoint the time and place of the annual meeting of the Supervisors";

(4) After the title "Censors," commence By-Law XX with the following additional provisions relating to supervisors:

The Censors, elected Supervisors, shall form a Board.

They shall elect their own Chairman.

The Recording Secretary of the State Society shall be their Secretary.

For the transaction of business ten Supervisors shall constitute a quorum.

They shall hold an annual meeting at such time and place as the Council shall direct; and may hold other meetings at such places and times as they may agree to appoint.

At their annual meeting, or adjournments thereof, the Supervisors shall formulate and adopt a uniform plan, consistent with the requirements of the By-Laws, to be pursued the ensuing year, by each District Board of Censors, in the examination of candidates.

They may authorize the Secretary to have printed, at the expense of the Society, all blanks and examination papers necessary to carry out their plans.

The Secretary shall furnish examination papers, to Su-

persors only, and in such number as each may, in writing, request.

It shall be the duty of each Supervisor to convey to the Board of Censors of the District Society to which he belongs, together with the necessary examination papers, a report of the method and spirit in which the Board of Supervisors have directed that their plan should be used, and to see that in all examinations the designated details are properly executed.

Should a candidate otherwise qualified, but without a diploma from one of the schools accredited by this Society, satisfy the Censors of the District Society where he resides, by examination, that he has received an education equivalent to that prescribed by the By-Laws of this Society, the Supervisor of said District Society shall present the name, standing and qualifications of said candidate, to the full Board of Supervisors at their next meeting, whereupon the assenting votes of two-thirds of the Supervisors present and voting, shall elect such a candidate to be a Fellow of this Society.

(5) By-Law XX to be changed by adding after the word "By-Laws," in line 2, the following, so that the By-Law shall read: "The Censors shall examine, according to the rules and By-Laws, and in conformity with the directions of the Supervisors," such candidates, etc.; also after the word "day," in line 21, by adding the following, "but not at the same hour or hours."

(6) By-Law XXI to be changed by substituting the word "supervising," for the word "senior," so that this By-Law shall read, "and the supervising Censor shall preside."

DR. J. C. WHITE, *President.*

DR. G. W. DOANE,	DR. J. F. A. ADAMS,
DR. F. A. HUBBARD,	DR. B. J. HANDY,
DR. R. B. ROOT,	DR. A. H. JOHNSON,
DR. A. C. DEANE,	DR. W. H. POMEROY,
DR. D. W. MINER,	DR. S. W. KELLEY,
DR. H. B. HOWARD,	DR. E. R. CUTLER,
DR. M. V. PIERCE,	DR. J. F. WELCH,
DR. H. F. BORDEN,	DR. J. H. MCCOLLUM,
DR. E. B. HARVEY,	DR. F. H. THOMPSON,

Committee.

After discussion by Drs. HARVEY, WILLIAMS, WHEELER, FRANCIS, F. C. SHATTUCK and CUTLER, it was voted:

That the report be accepted, and that the changes in the By-Laws, as far as the Council is concerned, be adopted.

The Librarian reported that, in accordance with the vote at the last meeting, the publishers were notified that no orders for future numbers of "Braithwaite's Retrospect" would be given, and that an acknowledgment of the receipt of the notice had been returned.

The Treasurer offered the following votes, which were adopted:

Voted, That the Librarian shall be the custodian of such papers, manuscripts and books of record belonging to the Society as are not in use by its officers. He shall properly catalogue them, and see that they are stored against the risk of fire. He shall arrange and file them in such a manner as to promote the convenience of Fellows of the Society who may desire to consult them. He shall include in his annual statement a report upon their condition.

Voted, That as the Censors are officers acting for the State Society, the different Boards of Censors are hereby directed to forward to the Librarian of the State Society such books of record as are not in present use.

On motion, the question of the reduction of the annual assessment was taken from the table.

Voted, That the subject be indefinitely postponed.

In accordance with notice given at the last meeting, DR. FORSTER moved, and it was voted, that Rule 2 of the Rules and Orders of the Councillors be annulled. The following was the rule in question:

"There may also be annually prepared, under the direction of the Councillors and at the expense of the Society, a retrospect of the medical literature and science of the preceding year, having reference especially to discoveries and improvements of practical value."

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON ORTHOPÆDIC SURGERY.

STATED Meeting, December 15, 1894, W. R. TOWNSEND, M.D., Chairman.

CONGENITAL TORTICOLLIS.

DR. ROYAL WHITMAN presented two cases of congenital torticollis complicated by induration of the sterno-mastoid muscles. The induration of these muscles was not the cause of the torticollis, but was secondary to it.

The first infant, now five months of age, was first seen at the age of three months. There was at this time well-marked left torticollis, hemiatrophy of the face, and congenital club-foot on the same side. In the middle of the contracted muscle there was an induration the size of a pigeon's egg. The labor was normal. The distortion of the head and the induration were noticed by the mother on the fourteenth day after birth. This induration in the muscle could still be felt, and the torticollis and hemiatrophy of the face were very evident.

The second infant, now seven months old, was first seen at the age of six weeks. Then, as now, there was marked torticollis, and an induration in the muscle, similar to that in the preceding case. In this case the child was delivered by forceps after a difficult labor. Immediately after birth the mother noticed the distortion of the head.

That the torticollis in the first case was of intra-uterine origin was shown by the hemiatrophy of the face and by the club-foot. That scar contraction had nothing to do with the deformity in the second case was proved by the fact that the deformity was noticed immediately after birth. Injury at birth might have caused the deformity, but not scar contraction following rupture of muscle. Simple rupture of a normal muscle, shown by induration, was not, as a rule, accompanied or followed by torticollis.

POTT'S PARAPLEGIA.

Dr. Whitman also presented a case of Pott's paraplegia in which a rather unusual form of paralysis was the very first symptom. About the first of last October the child, two years of age, was noticed to be stumbling; when first seen by the speaker, about two weeks later, there was not the slightest pain, and no angular deformity. The paralysis was of the flaccid type like that of anterior poliomyelitis. At the present time, two months after the appearance of the paralysis, there was still no angular deformity of the spine, although a change in outline due to muscular spasm was apparent. Within a week there had been complaint of pain, and the paralysis was now of the spastic type.

PERSISTENT PSOAS CONTRACTION.

Dr. Whitman presented still another patient, a boy nine years of age, who illustrated an extreme and persistent psoas contraction. When first seen, about two years ago, there was deformity of the mid-dorsal region, with slight psoas contraction; subsequently while under the care of an instrument-maker, an abscess formed, which opened spontaneously. The deformity of the spine was not well-marked, and the leg was firmly held at a right angle with the body. It was probable that an extensive tenotomy and fasciotomy would be required to bring it down to the normal line. He was inclined to think, that, if psoas contraction were allowed to persist, it exerted a very unfavorable influence on the deformity, because it was impossible to maintain by apparatus a proper attitude.

DR. V. P. GIBNEY said the occurrence of paralysis before the deformity was exceedingly rare, and in a series of fifty cases of Pott's paraplegia which he collected at one time, it was the rule for them to develop at first a little stumbling, but examination failed to show exaggerated reflexes until some time later. It was well to emphasize the fact, so apt to be overlooked by the general practitioner, that Pott's disease may occur without the pain or other usual signs described in the books. These are the slow cases of "caries sicca."

He did not agree with Dr. Whitman that it was necessary to treat the psoas contraction itself under ordinary circumstances. If one could exclude hip-joint disease, there need be no hurry about much treatment directed to the contraction.

DR. WHITMAN said that psoas contraction caused by true psoas abscess, that is, abscess within the sheath or substance of the muscle, was very likely to become permanent distortion, as illustrated by the case that he had presented — a distortion which made it impossible for the child to stand erect. Psoas contraction was best treated by temporary rest on the back, and by the direct treatment of the abscess which caused the contraction.

THE LORENZ TREATMENT OF HIP-DISEASE.

DR. V. P. GIBNEY presented a patient with hip-disease, who was being treated by the Lorenz method. This consists in applying a plaster-of-Paris spica bandage to a point midway between the knee and the foot, and then on the following day adding an iron stirrup which projects beyond the foot, and is secured by a starch bandage. It is claimed that with a high shoe on the sound foot the patient is able to go around easily. It would probably prove very useful where a good perineal crutch was not easily obtainable.

EXCISION OF THE HIP.

Dr. Gibney presented several cases of excision of the hip. The first one was that of John K., who was admitted to the hospital on October 8, 1892, at the age of eight years. The limb could then be flexed to 110° , and extended to 145° . After about one month of treatment in bed with the weight and pulley, a hip-splint was applied. On December 2d, an abscess was aspirated, but as it soon refilled and began to burrow, a partial arthrectomy was performed, and by the following February extension and flexion were nearly normal. On May 31st, he was discharged, still wearing the splint. There is now about one inch of shorten-

ing; flexion to nearly 90° , and extension to 170° ; the other motions are very fair, and the hip seems to be quite firm.

The second case was a boy admitted on October 12, 1891, at which time there was but a small range of motion. The disease began the year previous, and during that year he had an abscess. As there was marked abduction, it was treated with the Taylor abduction brace. On November 21, 1891, the limb could be extended to 170° , but the limb was everted. On January 6th it was noted that he was wearing a Thomas brace, and that there was much spasm and tenderness. An abscess on the anterior aspect of the limb was aspirated, and a few drops of pus removed. On May 17th, the trochanter major, with the head and neck of the femur, were removed. He remained in the country all the summer, and in the following November it was found that extension could be made to 180° and flexion to 110° . The next March an abscess formed in consequence of a fall, so it was incised and several ounces of pus evacuated. He was discharged the following September without a brace, but wearing a one-inch-high shoe. At present, the limb comes down straight, and can be flexed to 90° ; there is little resistance to abduction; there is slight adduction and rotation, and one inch shortening.

The third case was a boy who was four years old when his disease began in February of the present year. He was admitted in June; and in spite of repeated aspirations, a large abscess with marked deformity persisted, so that on November 10th, excision was performed. The wound healed very rapidly. On December 15th, a jointed Dowe's splint was applied.

The fourth case was a boy, five and a half years old, with a double hip-joint disease which began in May, 1891. His right hip was excised in Christ's Hospital, Jersey City, three months after the beginning of the disease. When first seen by the speaker the left hip was painful, and there was an abscess in this locality. The joint was excised on November 24th by posterior incision, and the head and neck removed. The case has done well.

These cases were presented to show that in hospital practice, there is a certain number which seem to require excision and which do well after it. None of the cases had a weak joint.

DR. A. M. PHELPS said he had seen this Lorenz brace applied many times. It was better than the Thomas splint, for it protected the limb, and it was superior to the long-traction splint, for the cases treated with it did not recover with the angular deformity so commonly seen after the use of the long-traction splint. The objections to the Lorenz splint were that it was cumbersome, that the patient walked upon it, and it did not apply extension in the line of the adductor muscles to prevent intra-articular pressure. With it abscesses were just as frequent as with the Thomas splint, and there was almost always shortening.

He heartily agreed with all that Dr. Gibney had said about the cases of excision. He had abandoned aspiration of abscesses, for eventually they must be incised. If by aspiration the presence of pus in a joint were detected, the sooner the abscess was incised, the better. By this means one was also enabled to explore the joint with the aseptic finger, and so determine whether or not an excision was required. No one could tell this from external examination alone. He favored the posterior incision and the removal of the

great trochanter in order to secure free drainage; in short, Dr. Sayre's method of leaving the periosteum and packing the wound with antiseptic gauze was still the best mode of treatment.

The CHAIRMAN dissented very emphatically from the opinion that the aspirator was useless, and that all these abscesses should be incised. In a series of cases of abscess which he had collected, nearly fifty per cent. were permanently relieved by aspiration. There were many abscesses situated near joints which were not intra-articular, and also many abscesses supposed to communicate with a joint until examined at the time of operation, when it was found that they did not.

DR. N. M. SHAFFER said no abscess was opened in the Orthopedic Hospital during the year; yet he would be perfectly willing to compare his results with those of Dr. Phelps.

DR. REGINALD H. SAYRE objected to the Lorenz treatment, as shown in this patient, on the ground that a good deal of pressure was borne by the hip, because part of the weight fell on the condyles of the femur instead of on the ischium. He had been much pleased with the cases of excision; and he would contrast the motion in these joints with the ankylosed joints which Dr. Whitman said at the last meeting the Germans considered to be superior. The European operators were not careful to save the periosteum.

DR. HALSTED MYERS said that in connection with this discussion he wished to report a case. A girl, when six years of age developed hip-disease; and two months later an abscess formed. After wearing a traction splint for six months, the joint was excised. She was kept in the hospital without a brace for a year, and was then discharged "cured." Soon after this she slipped, and another abscess developed. She was again admitted, and five months later was discharged cured. Three years after this she had another fall, and another abscess appeared, which was cured in three weeks. One and a half years afterward still another abscess formed, and was cured in four months. In September, 1893, or when she was fourteen years old, there was found to be three and one-quarter inches shortening, an increase of three-eighths of an inch in the last two years; there was also slight telescoping. The motions allowed in the joint were: flexion 180° to 140° , adduction 30° , abduction 10° , and considerable rotation. She had no abscess, no pain, and no longer wore a brace. She limped badly, but did not tire easily. The case seemed to show that after such excisions, the shortening might be steadily progressive, and also that all the disease was not removed at the time of excision, else there would not have been these frequent abscesses.

DR. WHITMAN said he had been misunderstood at the last meeting, for at that time he was speaking of excision done as a last resort, and not of the class of cases represented by the patients just presented. Reproduction of bone after excision, with a firm and movable joint, was a result to be hoped for, but not confidently expected.

DR. SAYRE regretted if he had misquoted Dr. Whitman; but he had himself recently noticed a number of German articles in which it was stated that a stiff joint represented the result which should be sought for after excision for tubercular disease of the hip.

DR. GIBNEY, in closing the discussion, said he regretted that Dr. Phelps still persisted in the belief

that every abscess in a tubercular joint should be incised. Regarding Dr. Myer's case, he said he did not see how the limb could grow when the upper epiphysis had been destroyed, whether by cicatricial tissue or by the removal of the epiphysis.

EXCISION OF THE TARSUS FOR CARIES.

DR. A. M. PHELPS presented a girl who had been brought to him at the Post-Graduate Hospital, two months before, with disease of the tarsus and the end of the tibia. At the operation it was found that the disease involved the astragalus, os calcis, cuboid and scaphoid bones, as well as the ends of the metatarsal bones and the end of the tibia, so these parts were all removed, leaving a shell of bone with the periosteum. At the end of six weeks the case was dressed, and it was then found that there had been perfect reproduction of the entire tarsus, and of nearly all of the metatarsal bones, together with the end of the tibia. Finding a metastasis in the scapula, the spine of this bone was removed.

DR. GIBNEY said he had treated very successfully a number of cases of extensive disease of the entire tarsus without operation. The results were perfect in the great majority of such cases.

DR. S. KETCH said that very badly diseased tarsæ were often cured by simple protection and avoidance of traumatism and pressure. It had been his experience that disease of the ankle-joint was usually followed by better functional results than disease of the other articulations.

DR. PHELPS said that when, on cutting into the tarsus the bones were found separated and necrotic, he thought no protection would be of much importance.

LAMINECTOMY FOR TUBERCULAR DISEASE OF THE SPINE.

DR. CARL BECK presented a patient on whom he had performed laminectomy. He was first seen two years ago, and was then three years old. Resection of the shoulder was first performed for the removal of tubercular foci in the humerus. One year later it was found that there was some rigidity and pain in the spine. He was treated for some time in one of our hospitals, and when he came again to the speaker, it was found, on removing the plaster dressing that there was a kyphosis. He was greatly emaciated, and there was a large fluctuating tumor in the left gluteal region. An incision was made into this abscess; and after inserting a drainage-tube and gauze, he was placed in a Rauchfuss apparatus. After three weeks, a plaster jacket was applied, and he was treated as an out-patient. Soon after, a prominent kyphos appeared at about the ninth dorsal vertebra, and the child had paraplegia. An incision was made from the seventh to the last dorsal vertebra; and on exposing the spinal cord, it was found that the meninges were hyperæmic and thickened. Free drainage was established for the abscess, and the fistulæ curetted and packed with gauze. He was again placed in the Rauchfuss apparatus. His condition had greatly improved since the operation, and he hoped that eventually the child would be able to discard the plaster jacket. The open treatment, the speaker considered the treatment *par excellence*.

Dr. Beck then exhibited a new instrument for use in connection with these abscesses; he called it "the irrigation trocar."

A NEW OPERATION FOR THE RELIEF OR CURE OF ROTARY LATERAL CURVATURE OF THE SPINE. PROPOSED FOR DISCUSSION OF THE SECTION.

DR. SHAFFER read a short paper describing a new operation which he proposed for the relief and cure of rotary lateral curvature of the spine. After having performed it several times on the cadaver, he had proposed it in a certain case of a young girl, when the rotation had progressed steadily and persistently in spite of all that could be done with mechanical treatment, exercises, etc. The surgeons to whom he had proposed the operation, in formal consultation, did not approve of the procedure, not that the surgical risk would be so great, but rather on account of our present imperfect knowledge of the pathology of these persistent and inveterate curves. Under these circumstances he brought the subject before the Section for discussion.

The operation proposed is as follows:

A large curved incision is made, which extends from one inch above the upper end of the pathological curve to one inch below it. An incision is now made through the trapezius muscle, which with the superficial tissues is dissected off until the erector spinæ is fully exposed. This is now divided transversely, as many transverse incisions being made as there are intervertebral articulations to loosen. The fibrous tissues between the transverse processes are divided so far as possible. A curved director is then passed under the costo-transverse ligament, which is divided with a blunt-pointed, curved bistoury. All the accessible soft parts having now been divided, a forceps lever is placed between the transverse processes, and they are gently forced apart. In the cadaver, after the costo-transverse ligament was divided, it was found that the articular processes could be easily forced apart, and the vertebræ separated on the concave side of the curve.

In the cadaver it seemed easy to avoid the spinal artery and nerve, and with care there seemed to be no danger of wounding the pleura.

In view of the recent operations upon the spinal column, it seemed to the reader of the paper that the proposed operation was both feasible and justifiable, especially as applied to rotary curves of an inveterate type, if recognized in the early stage.

DR. WHITMAN said the case of Dr. Beck was evidently suffering from double psoas contraction, and that as the attitude exaggerated the deformity, the treatment should be rest on the back.

DR. PHELPS said he had done seven laminectomies—two for Pott's disease, and five for fracture. The latter had yielded more favorable results. He believed laminectomy should be performed in cases of Pott's disease where paralysis was present, where there was incontinence of urine or feces, and where there were abscesses and every indication of extensive disease of the bone.

DR. SAMUEL LLOYD had been much interested in this case. The latest statistics showed that 103 laminectomies had been performed for Pott's paraplegia simply. Dr. Phelps has summed up the indications for operating well, but had applied Lauenstein's rule too rigidly, as this rule had never been intended to apply to other than traumatic cases. The number of cases requiring laminectomy was very few, and the operating surgeon should not attempt to operate until

he had satisfied himself that efficient mechanical treatment had been employed previously without success.

Dr. Shaffer would find a good precedent for his operation in those operations which had been done for rotary and lateral dislocations of the spine. As the pleura was thickened, it was likely to be pushed aside out of harm's way, and the hæmorrhage should be the same as in laminectomy, that is, it should be readily controlled by packing.

DR. KETCH said he did not consider laminectomy for Pott's disease a justifiable operation except where it was done as a life-saving measure. He agreed with the last speaker that the continuance of paraplegia or the presence of incontinence of urine and feces were no guides to the operation. He thought most of the cases of Pott's disease operated upon would have done just as well without operation.

DR. I. S. HAYNES said that it should be remembered that a thick layer of tendinous fibres was present, and should be thoroughly divided in a number of places. Again, nothing could be gained until the anterior costo-transverse ligament had been completely divided. No arteries of importance were encountered. Primary union was very desirable, for if healing occurred by granulation, the cicatricial contraction would only serve to aggravate the original condition.

[Discussion to be continued at next meeting.]

Recent Literature.

Anæsthetics: Their Uses and Administration. By DUDLEY WILMOT BUXTON, M.D., B.S., Member of the Royal College of Physicians; Member of the Royal College of Surgeons of England; Administrator of Anæsthetics and Lecturer in University College Hospital, the National Hospital for Paralysis and Epilepsy, Queen's Square, and the Dental Hospital of London. Second edition. Philadelphia: P. Blakiston, Son & Co. 1892.

This is the second edition of this work, which has done much towards systematizing our knowledge of anæsthetics. It is written from a historical as well as a practical standpoint; but while many different forms of inhalers are shown, the author has not given the advantages or disadvantages of each apparatus. The author's conclusions regarding the value of different anæsthetics are judicious. The effect of chloroform is well described.

The book will well repay perusal by those administering anæsthetics.

A Practical Treatise on Nervous Exhaustion (Neurasthenia): Its Symptoms, Nature, Sequences, Treatment. By GEORGE M. BEARD, A.M., M.D. Edited, with notes and additions, by A. D. ROCKWELL, A.M., M.D. Third edition, enlarged; 8vo, pp. 262. New York: E. B. Treat. 1894.

To the third edition of this well-known work the editor has added a brief chapter on the etiology and pathology of nervous exhaustion. In this chapter he speaks of the changes in the nerve cells caused by fatigue, and points out the relations such changes may bear to neurasthenia. He also touches upon the influence which the conditions of American life have in producing the disease.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 1, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

FEEBLE-MINDED CHILDREN.

SIR DOUGLAS GALTON has written an interesting article in the *Nineteenth Century*, in which he calls attention to the importance of making special provision in the elementary schools for training those children who are more or less defective, or who are suffering from mal-developments which are associated with defects in the brain.

To Dr. Francis Warner belongs the credit of having suggested methods for carrying into effect an inquiry into deviations from the normal in children in various London elementary schools. He has now reported on over 80,000 children seen individually by him in 148 schools, having taken notes of all cases presenting any visible defect, that is, 14,297 children. The method of procedure was as follows: "As the children stand in rank, each is viewed separately, without being touched, or questions asked. The child is then directed to imitate a few simple movements. Any deviation from the normal in bodily development or in conformation of the head or a feature is recorded; also any abnormality in expression, balance, movement of the eyes, or action in the hand or fingers is noted as an 'abnormal nerve-sign,' indicative of the state of the nerve-system, and these particulars are recorded in schedule forms." A full description may be found in the "Report on School-Children," by Dr. Warner, to the Charity Organization Society, 1892.

Statistics of the first 50,000 children seen (1890-1891) have been arranged and presented to the Local Government Board; this report is now published by the Bureau of Education, Washington, D. C.

Four primary groups of cases were easily arranged: "development cases," including all children presenting one or more defects; "nerve cases," each child presenting one or more "abnormal nerve-signs"; "nutrition cases," children pale, thin, delicate; "dull children," as reported by the teachers in school.

The same children often appear in more than one group; thus, of the "development cases," 52 per cent.

also presented abnormal nerve-signs; and of the "nerve cases," 60 per cent. were also "development cases." Of the children "pale, thin and delicate," 71 per cent. of the boys, and 74.6 per cent. of the girls were also "development cases." In these figures, we see the physical co-relation of congenital defective development producing a tendency to nerve-disturbance and low nutrition of body.

In all schools, a larger proportion of boys than girls deviate from the normal. There is, however, a rather larger proportion of girls who are "pale, thin and delicate"; and congenital weakness in constitution, however slight, renders a girl more likely to ill-health than a boy; and any nerve disturbance occurring in her is more liable to be rendered permanent than in the boy. When, however, we take boys and girls presenting no defect in development, we find the proportion who are delicate equal in both sexes. Let the teacher then, arrange the curriculum for the normal girls, and modify it when necessary for the weaker members. Neglect of the latter precaution may lead to deplorable results; but the whole level of the school need not be lowered to the capacity of the weaker pupils.

One defect stands prominent among the girls: cranial abnormalities have the highest co-relation with defectiveness of health and brain power. The sub-class "small heads" forms 3.4 per cent. among English girls, as compared with 1.3 per cent. for boys, and is largely attended with mental dulness, low nutrition, and abnormal nerve-signs. Of girls in industrial schools, 6 per cent. were "small headed"; this condition is more common among the children of large blocks and warehouses.

Many points of direct educational importance have been elucidated. It has been shown that of the group of children presenting abnormal nerve-signs, 41 per cent. are dull mentally; and in a varying degree the same may be said of children presenting each separate nerve-sign. As examples: many children do not move their eyes properly in looking at objects, but turn the head toward the point looked at in place of moving the eyes; 43 per cent. of these children were reported as dull by the teachers, they are bad readers and bad observers. If this condition is known to the teacher, the fault may be corrected; eye-movements should be trained in the kindergarten.

A listless attitude in the pupil is not conducive to mental aptitude, but it is not generally understood that a good balance of the body in every detail, even to the hand and fingers, promotes in the brain an aptitude of mental brightness, and that cultivation of symmetry and accuracy in movement and attitude promotes a healthy brain state; yet such appears to be the truth. In removing abnormal balances and action in movement, the teacher helps to improve the activity and balance of brain.

It is most commonly among boys that we see frowning, or the formation of horizontal creases on the forehead by muscular action; this is very common among

imbeciles — and it may be added, in monkeys also. Now such a boy will often cease to frown when he is interested; that lesson improves his brain during which frowning ceases. This condition is much more frequent among boys in the monotonous life of the Poor-Schools than in the elementary day-schools. It is the "development cases" that tend the most to defectiveness of brain-power and to low nutrition; such cases do the best in the day-schools. Their educational neglect tends to fill the ranks of pauperism, criminality, and the unemployed.

In one school, fourteen children were promptly taken to the Ophthalmic Hospital for correction of squint and other defects; their needs had not been noticed before.

The number of children presenting defective condition of the eyes is large; uncorrected squint is very common, and though this defect is often preventable by the use of spectacles, comparatively few pupils use them among those who ought to. Eye-diseases in all stages, often contagious cases, were seen in many day-schools, and other examples of preventable conditions. Here is a large field for good work. The want of correction of faults by the teachers, and neglect of cases needing medical treatment probably arise mainly from ignorance of existing conditions; but it may be hoped that a more widely spread attention to the study and observation of children among all classes will inspire a more intelligent interest in their care and training.

Defectiveness of body, brain-weakness and low nutrition are evils confined to no social class; it appears, on comparing the conditions of 10,000 children in schools of the middle and upper social classes with 26,000 children in poorer day-schools, that in each of the four primary groups of defects the proportion goes against the children of the upper class. This is very surprising and needs further inquiry.

The greater the number of visible defects in a child, the greater is the probability of its being dull; so that of children appearing in three of the primary groups of defects, 44 per cent. were said to be mentally dull.

The children presenting certain of the "abnormal nerve-signs," are those commonly called nervous children; they are usually intelligent and quick at lessons; they are imitative and gregarious. Whether it is advisable to allow such children to sit together at school is questionable; on the other hand, dispersed among the more average pupils, they tend to impart their quickness.

It has been shown by observation that spontaneity is the foundation of intelligence, yet the attempt is often made to keep young children quiet and almost motionless — often destroying spontaneity in place of co-ordinating it. The endeavor should be to encourage spontaneity, and to co-ordinate it to intelligent action adapted to the age of the child.

Spontaneity of movement to the extent termed *idgetiness* is often the result of fatigue and exhaustion; if teachers were acquainted with the signs of

fatigue, they could better control the child's condition. Fatigue in children is common; it may be the result of bad sleep, late hours, excitement of home life or school work. The signs of fatigue may be marked in the morning and lessen during the hours of school; or they may be most apparent in a certain class-room, if it be ill-ventilated and overcrowded. There is a small class of pupils presenting well-made bodies and well-acting brains who are said by teachers to be very dull, and doubtless this is true. Such children should not be discouraged; they may become useful members of society, and need not be treated exceptionally; though they have often been spoken of as idiotic, which is not true; and it is discouraging to give them a bad name.

Galton's article is full of valuable suggestions, showing that a more exact knowledge of the physical and mental conditions existing among children is needed. The scientific principles which have enabled the observer to detect the various degrees and items of mental weakness already point the way to their removal; and were instruction in such studies given to teachers and others, the methods of classification and training might be reduced to better order and adapted to the needs of groups of children.

THE INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY, VOL. XIV.

THE latest contribution to the Index Catalogue cannot be passed without notice, though this present volume was issued several weeks ago. It completes the Index through the word "universally."

The Index Catalogue has been published now for so many years that one grows retrospective in the contemplation of another volume. Perhaps no publication of recent years has done more for the general good of the profession than this. Its influence has been felt in many directions and it is by no means easy to define exactly its effects. Perhaps they show themselves chiefly, but by no means exclusively, in our literature. The knowledge of previous writings on any subject is more easily gained as the Index approaches completion, and in consequence the writings of our forbears is less often overlooked; and medical men have gained the habit of looking at their unusual cases as but the experience of a single man which needs to be compared with similar experiences on the part of others, in order that it may have its proper value. In this way the classification and knowledge of unusual cases has increased.

One thing is very noticeable. The "Curious Cases" have vanished from our periodical literature, certainly from the more important journals. Authors and editors have learned that the title of a medical paper must give some clue to its contents if the case is to have any value beyond a mere curiosity and the facts narrated are to be of any service. Many a case which might be considered as absolutely unique is found to be but a repetition of previous experience by reference to

records which are made accessible by this Index. It must also be said that the value of genuine observations is made manifest, and thus the record of cases is encouraged.

Medical libraries have grown in a way hitherto unequalled since the Index Catalogue has given an added value to their contents; yet it is rumored that the principal promoter of this valuable work has said, we presume in a careless moment, or at a time of such self-depreciation as occasionally comes to all busy workers, that he would rather have done a single piece of original work, however small, than have compiled this Index.

In one of the best regimental histories of the late war, the editor speaks as follows of some of his old comrades:

"We know men in the Thirteenth . . . with a record that every man who respects courage and fortitude under trying circumstances would be glad to take off his hat to when meeting them on the street, but only their comrades know what soldiers they were. You never hear them mention the fact, for they see nothing heroic in anything they did themselves, while they imagine that every man did something better."

This quotation does not seem out of place here, for it illustrates the way in which modest men often regard their own accomplished deeds.

One of the interesting things one finds in this volume is the catalogue of testimonials to the qualifications of eminent aspirants for medical appointments—a collection which must be of equal value with the portraits of medical men; though it is doubtful if any hint of the human frailties inevitable to us all could be found in these testimonials.

MEDICAL NOTES.

AMERICAN VISITORS AT THE INTERNATIONAL MEDICAL CONGRESS.—Prof. N. J. Johnston-Levis, of Chiatamone, Naples, desires to inform American visitors that he will be pleased to aid and advise those medical gentlemen who will visit Naples at and about the time of the International Congress.

SMALL-POX IN A PITTSBURGH HOSPITAL.—A case of small-pox occurred this week in a general ward at the West Pennsylvania Hospital in Pittsburgh, and the board of health has ordered a quarantine of the hospital, which contains some 950 patients and over 100 nurses.

INTERNATIONAL SANITARY CONFERENCE.—The International Sanitary Conference at Paris has already formulated a series of measures to prevent the Mecca pilgrims from spreading the cholera. The subject of immigration to this country, which was suggested by the United States delegates, was laid aside for later consideration as not falling within the primary purpose of the conference.

THE RUSSIAN JAMBUL COMMISSION.—The Russian Government has sent a commission composed of physi-

cians to Asia Minor to inquire into the properties of the jambul plant, which has been reported to have marked efficacy in cases of cholera.

RESIGNATION OF DR. LATHAM.—Dr. Latham has resigned the Downing Professorship of Medicine in the University of Cambridge, England, after having held the post for twenty years.

THE WONDERFUL JICAMA ROOT.—The discoverer of the Mexican Jicama root, which has been found useful in cases of typhus fever, claims now that it will cure small-pox and yellow fever. The list is not yet extended further.

SEPTICÆMIA IN THE EDINBURGH MATERNITY HOSPITAL.—The Edinburgh Maternity Hospital has been temporarily closed in consequence of an epidemic of septicæmia. Several consecutive cases occurred recently; and no new patients have been admitted for the present.

FIRES IN ASYLUMS.—Two fatal fires have occurred the last week in asylums where great care should be exercised. One in the laundry building connected with St. Vincent's Male Orphan Asylum at Albany, N. Y. There were 130 boys in the main building who were at no time in immediate danger. The other fire was more serious and occurred at the New Jersey Training School for the Feeble-Minded in Vineland, N. J. The Robinson Memorial Cottage was totally destroyed and the inmates were rescued with some difficulty. The engineer and his wife were burned to death.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—During the eight days ending at noon, February 28th, 1894, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 35, scarlet fever 54, measles 19, typhoid fever 18, small-pox 12. There were four deaths from small-pox.

SMALL-POX IN MASSACHUSETTS.—During the week ending at noon February 28th, but two cases of small-pox have been reported to the State Board of Health from places outside of Boston, one each in Lawrence and Holyoke.

THE ANNUAL REPORT OF HARVARD COLLEGE: THE MEDICAL SCHOOL.—The report of the Dean of the Medical School in the annual report of Harvard College states the falling off in the number of matriculants this year—due probably to the change to a four years' course which went into effect at the beginning of last year—at twenty-five. Owing, however, to the large size of the higher classes the total number of students in the school will not be diminished. The diminution of the percentage of college graduates in the entering classes, previously noted and discussed, still continues. The causes of this, whatever they may be, are still operative. The percentage, having, between 1884 and 1892, fallen from 53.9 to 28.2, has in the present year dropped to 23. The President of the University directs the serious attention of the two

Governing Boards and of the University Council to this tendency, which, in his estimation, threatens the best interests both of the school and of the community. The school is in a sound financial position, and the total expenditure for salaries, which in 1891-92 was \$47,212, has been raised in the year 1892-93 to \$67,112. During the year a laboratory of experimental therapeutics has been established for carrying on original investigations and for training advanced students in pharmacological research.

THE DENTAL SCHOOL. — The number of students in the Dental School is steadily increasing; there were fifty-three matriculants the past year. The instructors continue their diligent and self-sacrificing devotion to the interests of the school. A new building with increased accommodations and greater facilities is more and more needed with the increase in the number of students. The attempt made a year ago by the Faculty and friends of the school to raise a building fund, started under favorable auspices, but has been much interfered with by the prevailing financial depression. The fund now amounts to \$18,000, and \$20,000 more are urgently needed for the purchase of a desirable lot which the Faculty has in view.

THE VETERINARY SCHOOL. — The encouraging growth in the number of students previously noted, has been fully maintained. But the school is in great need of endowments for prosecuting its educational work to advantage. The annual deficit in the finances of the school is made up from the receipts of the hospital, the work of which is thereby restricted. The Dean gives expression to this need in the following closing sentences of his report: "I feel that I must lose no opportunity of urging the endowment of this totally unendowed school. As has been shown, we can use even a few hundred dollars a year to great advantage; for we have here a well-founded institution, at which a science of the widest usefulness to mankind, and the greatest humanity to dumb animals, is being well and thoroughly taught to good classes of bright and earnest young men; but this established institution is sorely in need of more room in which to carry on the work which its own prosperous career has brought it. It certainly seems remarkable to one who knows what has been accomplished by this department of the university during its short life, and how much need there was that the subject should be taken up by a strong American university, that among all the generous givers to the higher education, among the many who are interested in questions of public health, and among all those who love horses and dogs, none have yet been found willing to give us material financial support. The school is not an experiment; it is an assured fact. Where else has a scientific school, in any subject, ever been established that has fought the battle of the higher against the lower education successfully without endowment of any sort?"

FIRE IN A NEW HAMPSHIRE INSANE ASYLUM. — A fire occurred in the Rockingham County (N. H.) Insane Asylum last Sunday, but was fortunately ex-

tinguished with small loss. No cause has been discovered for the fire.

SMALL-POX IN WATERBURY, CONN. — A case of small-pox was discovered on Monday in Waterbury, Conn., in a house occupied by six families aggregating twenty-nine persons.

NEW YORK.

TUBERCULOSIS IN CATTLE. — It is said that there are at present about twenty thousand head of cattle in the State which are affected with tuberculosis and have been condemned by the health authorities, but which cannot be destroyed for lack of funds to accomplish this object and compensate the owners. A bill has recently been introduced into the Legislature providing for an appropriation for the purpose of awarding proper compensation to those whose cattle it is found necessary to kill on account of this disease.

A CASE OF TRAUMATIC PULMONARY TUBERCULOSIS. — An interesting case of pulmonary tuberculosis, the exciting cause of which was traumatic in character, has just terminated fatally in the person of Dr. Robert N. Manney, a veterinary surgeon residing at Morrisania, in the annexed district of this city. Two years ago Dr. Manney got into an altercation with a blacksmith, and was stabbed in the side by the latter. The knife penetrated one of his lungs, and as a result of this injury tubercular disease eventually developed.

ST. MARK'S HOSPITAL. — The new building of St. Mark's Hospital, on Second Avenue, near Eighth Street, was formally opened on February 17th. The building can accommodate about sixty patients, and the operating facilities of the hospital are of an admirable character.

THE GERMAN HOSPITAL TRAINING SCHOOL FOR NURSES. — The large new building erected for the Training School for Nurses of the German Hospital, at Seventy-fourth Street and Park Avenue, was opened with appropriate ceremonies and a reception on February 22d. It is five stories in height and is ninety-five feet long and twenty-five feet wide. There are two entrances upon the hospital grounds and from the basement a tunnel extends to the main hospital building. On the first floor are the apartments of the superintendent and his family, as well as a large lecture room, and the rest of the building has been fitted up for the accommodation of the pupils, forty in number. The cost of the structure was \$72,000.

MEMBERSHIP OF THE NEW YORK COUNTY MEDICAL ASSOCIATION. — At the last meeting of the New York County Medical Association, held February 19th, Dr. S. B. W. McLeod, who has been re-elected President for another year, delivered his annual address. In the course of it he gave an interesting review of the growth and history of the Association during the first decade of its existence. At the time of its first meeting for scientific purposes there were 109 members, and there are now over 950 on its roll. The first paper read before the Association was by the late Prof. Austin Flint, on "Pathological and Practical

Relations of the Doctrine of the Bacillus Tuberculosis." The meeting occurred January 14, 1884. During the ten years 75 members have been removed by death.

Miscellaneous.

A BILL RELATIVE TO VACCINATION.

THE following bill, relative to vaccination, was introduced in the Massachusetts Senate by Senator Harvey, of Worcester, and has been referred to the Committee on Public Health:

SECTION 1. Parents and guardians shall cause their children and wards to be duly vaccinated before they attain the age of two years. For every year's neglect, the party offending shall forfeit the sum of ten dollars.

SECT. 2. The board of health in any city or town shall require and enforce the vaccination and re-vaccination of all the inhabitants thereof whenever in the opinion of said board the public health or safety requires such action. Every person over twenty-one years of age, not under guardianship, who neglects to comply with such requirement, shall forfeit the sum of ten dollars.

SECT. 3. The board of health in any city or town shall furnish the means of free vaccination or re-vaccination to all the inhabitants thereof whenever in the opinion of said board the public safety requires it.

SECT. 4. Incorporated manufacturing companies, superintendents of almshouses, State reform schools, industrial schools, lunatic hospitals and other places where the poor or sick are received, masters of houses of correction, jailers, keepers of prisons, the warden of the State prison and superintendents or officers of all other institutions supported or aided by the State, shall, at the expense of their respective establishments or institutions, cause all the inmates thereof to be vaccinated or re-vaccinated whenever in the opinion of the board of health, in the city or town in which such establishments or institutions are situated, the health of the inmates thereof or the public safety requires such action.

SECT. 5. Sections fifty-one, fifty-two, fifty-three, fifty-four and fifty-five of Chapter eighty of the Public Statutes are hereby repealed; *provided*, that nothing herein contained shall be construed as affecting any action that may be pending under said sections at the time of the passage of this act.

Our readers will find the substance of the existing law stated on page 22 of this volume of the JOURNAL.

ACTING ASSISTANT SURGEONS.

THE Association of Acting Assistant Surgeons has been endeavoring for some time to have Congress remove a technical disability of rank which prevented the members from obtaining admission to certain organizations. A bill has been introduced in both the Senate and the House of Representatives which is intended to provide for such cases. The following extract from the preamble and the bill will show its purpose.

"Whereas, Because these acting assistant surgeons were not commissioned as officers, but were employed by contract as such, they are denied admission to military organizations like the Loyal Legion and the Grand Army of the Republic; and to relieve this unjust discrimination, and to give a proper recognition to their patriotism, duties, responsibilities, services, hardships and exposures, they ought to be entitled to receive the rank for which they are allowed

pensions and which will relieve them from these disadvantages. The appended bill is offered for this purpose. It involves no expense to the United States Government and no change in the relative rank of officers of the medical corps of the United States Army who have been or are now in the service of the United States; Therefore,

"Resolved, That private physicians who were employed as medical officers in the armies of the United States for a period of not less than three months, and who were known officially as acting assistant surgeons of the United States Army, and whose services were honorably terminated, shall be commissioned by the President of the United States as acting assistant surgeons of the United States Army; and the date of employment as acting assistant surgeons to be the date of commission and muster into service, and the date of the honorable termination of service as acting assistant surgeon to be the date of discharge or muster out of service;

"Provided, That no pay or allowance shall be made to any such acting assistant surgeon by virtue of this act; and this act shall not affect the rank, pay, or emoluments of commissioned medical officers of the United States Army."

SUICIDE IN NEW YORK.

THE Committee of the New York Medico-Legal Society appointed to consider the repeal of the existing law in New York relating to suicide have submitted the following report:

We recommend the repeal of the existing law punishing unsuccessful attempts at suicide, for the following reasons:

(1) It is wholly indefensible from the standpoint of this great principle, that all penal laws should have for their object the deterring rather than the punishment of crime.

(2) It in effect repeals the former laws making suicide a crime, and makes its unsuccessful attempt punishable only; so that its effect is to stimulate the would-be suicide to higher efforts towards self-destruction to avert the punishment it visits only upon failure.

(3) The act, therefore, instead of serving as a deterrent to the commission of crime, which should be the aim of penal legislation, is one which, in its whole scope and effect, incites to and probably actually increases the volume of this crime.

(4) Civilization, in the recent centuries, has regarded and treated suicide as a crime, and has attempted to so frame its penalties as to act as a deterrent upon the minds of those who sought or have contemplated it.

The majority of mankind would be influenced by any post-mortem punishment that would bring disgrace or reproach upon the names, family, or friends of the suicide.

The existing statute ignores the universal recent judgment of the race in relieving the successful suicide from all such restraints, with their conceded deterrent effects.

(5) A large proportion of suicides are confessedly those laboring under insane delusions. Unsuccessful attempts by such, under the existing statute, are pitiful examples of the incongruity and unwisdom of the law in its practical operation.

(6) It is claimed, and with great propriety, that the present statute is practically inoperative.

We respectfully submit that this enactment should no longer remain among our criminal statutes.

IN MEMORIAM.—SAMUEL M. DONOVAN, M.D.

QUINCY, MASS., February 20, 1894.

A breath of spring is in this winter morning; but its sweetness is tinged with profound sadness that Dr. Samuel M. Donovan whom so many have known so long as physician and friend, lies in the silence of death. His sunny

smile and cheery welcome are among the valued recollections of the past. With an accomplished mind that led him to a conscientious absorption of what his profession taught him, was a rare, refined taste that embraced whatever was fine in art, music and science. His acquaintance with roses was a particular element; and while we, duller, knew and loved them as roses; he had the species and variety of each especial flower at tongue's end.

Tenderness in him was of a delicate quality, especially towards children. "His quiver was full," but he did not pass by any child slightly. Meeting him one morning with his buggy crammed full of little ones, we pointed to one, asking, "Are they all yours?" "No," said he, "that one is not." "Why," said we, laughingly, "have you not enough of your own?" "Well" was the answer, "that little chap saw us, and wanted a ride, so I took him in." Lately, speaking of illness and weakness, he said, "I ask one thing, to see all my children grow up to be fine." Now, the little light-haired, blue-eyed brood are fatherless.

His ready assimilation of medical knowledge made him a valued physician. He was a fond husband and a good friend. He was prominent in our charitable work and among our poor. We were not ready to spare him; but resting in the hope that if his brief life had incompleteness here, and trusting that it will find full completeness in the beyond to which he precedes us, we lovingly, respectfully, lay this memento of a friend of many years, upon his bier.

A. E. F.

Correspondence.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA. COMMITTEE ON SCIENTIFIC BUSINESS.

PHILADELPHIA, February 15, 1894.

MR. EDITOR:—At its last meeting the Medical Society of the State of Pennsylvania appointed—under the provisions of a by-law proposed at Harrisburg and adopted at Williamsport—a Committee on Scientific Business, "to secure scientific papers and to provide scientific discussions for each annual meeting, and to co-operate with the Committee of Arrangements and Credentials in arranging the programme." The members of this Committee are Drs. Dulles, of Philadelphia; Gorgas, of Harrisburg; LeMoynes, of Pittsburgh; Tyson, of Philadelphia; and Towler, of Marienville. The object of this change in the law is to have a permanent committee which, becoming familiar with the subject, shall find it easier to secure good scientific work than is possible for a committee that is appointed new every year.

The Committee on Scientific Business is working in conjunction with the Committee of Arrangements, of which Dr. E. E. Montgomery is Chairman, and will co-operate with it in arranging the programme.

The Committee hopes that each member of the State Society will aid it in attempting to make the meetings of the Society of greater scientific importance than they have been in the past. To this end the Committee will welcome suggestions from any member of the Society and especially, at this time, offers of contributions to the work of the next meeting at Gettysburg, May 15th to 18th. It is desired that there should be as many brief, concise, practical papers as possible; and it is proposed to have a discussion on "Tuberculosis," devoting the morning to "Medical Tuberculosis," and the afternoon to "Surgical Tuberculosis."

Any communication from members of the Society in regard to the work of the Committee, will be welcomed by it.

Members of the Society desiring to read papers, or to take part in the discussion on Tuberculosis will please notify the Chairman of the Committee,

DR. CHARLES W. DULLES,
4101 Walnut Street, Philadelphia.

METEOROLOGICAL RECORD.

For the week ending February 17, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,521: under five years of age 919; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 441, acute lung diseases 504, consumption 304, diphtheria and croup 153, scarlet fever 57, measles 35, typhoid fever 32, diarrhoeal diseases 30, cerebro-spinal meningitis 22, whooping-cough 19, small-pox 18, erysipelas 15.

From typhoid fever Chicago 9, Milwaukee 5, New York 4, Cincinnati, Lawrence and Cleveland 3 each, Pittsburgh 2, Brooklyn, Boston and Cambridge 1 each. From diarrhoeal diseases New York 11, Chicago 4, Brooklyn and Milwaukee 3 each, Cleveland and Fall River 2 each, Boston, Worcester, New Bedford, Pittsfield and Marlborough 1 each. From cerebro-spinal meningitis New York and Chicago 5 each, Brooklyn, Cleveland, Lynn and Somerville 2 each, Worcester, Gloucester, Quincy and

Marlborough 1 each. From whooping-cough New York 5, Brooklyn and Boston 4 each, Cincinnati, Milwaukee and Fall River 1 each. From small-pox Chicago 13, New York 5. From erysipelas Chicago 6, New York 5, Boston 2, Brooklyn and Nashville 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending February 10th, the death-rate was 19.1. Deaths reported 3,830; acute diseases of the respiratory organs (London) 372, whooping-cough 138, diphtheria 89, measles 76, scarlet fever 46, fever 43, diarrhoea 33, small-pox (Birmingham 4, West Ham, Halifax and Bradford 1 each) 7.

The death-rates ranged from 12.1 in Croydon to 26.5 in Bristol; Birmingham 22.6, Bradford 16.3, Brighton 15.8, Huddersfield 18.0, Hull 21.8, Leeds 18.5, Leicester 13.5, Liverpool 24.2, London 18.4, Manchester 21.7, Newcastle-on-Tyne 18.6, Nottingham 20.5, Portsmouth 17.1, Salford 19.0, Sheffield 18.6, Swansea 19.7.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 17, 1894, TO FEBRUARY 23, 1894.

FIRST-LIEUT. BENJAMIN L. TEN ETYCK, assistant surgeon, U. S. A., will report in person to COLONEL JOSEPH C. BAILY, assistant surgeon-general, president of the examining board appointed to meet at Fort Sam Houston, Texas, at such time as he may be required by the board for examination as to his fitness for promotion.

A board of medical officers to consist of COLONEL CHARLES H. ALDEN, assistant surgeon-general; LIEUT.-COL. WILLIAM H. FORWOOD, deputy surgeon-general; MAJOR CHARLES SMART, surgeon; MAJOR WALTER REED, surgeon; CAPTAIN JAMES C. MERRILL, assistant surgeon, is constituted to meet at the Army Medical Museum Building, Washington, on the 12th of March, 1894, at ten o'clock A. M., for the examination of candidates for admission to the Medical Corps of the Army.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FOUR WEEKS ENDING FEBRUARY 17, 1894.

MURRAY, R. D., surgeon. To proceed to Key West, Fla., for special duty. January 26, 1894.

BAILLACHE, P. H., surgeon. Granted leave of absence for twenty days. February 6, 1894.

PURVIANCE, GEORGE, surgeon. Detailed as chairman, Board of Examiners. February 12, 1894.

STONE, G. W., surgeon. Detailed as member, Board of Examiners. February 12, 1894.

CARTER, H. R., surgeon. To report at Bureau for temporary duty. February 2, 1894. To proceed to Brunswick, Ga., Quarantine as inspector. February 6, 1894. Detailed as recorder, Board of Examiners. February 12, 1894.

WHITE, J. H., passed assistant surgeon. Granted leave of absence for seven days. February 17, 1894.

CARRINGTON, P. M., passed assistant surgeon. Granted leave of absence for thirty days. February 19, 1894.

BRATTON, W. D., passed assistant surgeon. Granted leave of absence for thirty days. January 20, 1894.

PETTUS, W. J., passed assistant surgeon. Granted leave of absence for thirty days. January 30, 1894.

VAUGHAN, G. T., passed assistant surgeon. To report to the Secretary of the Treasury for special duty. January 26, 1894.

YOUNG, G. B., assistant surgeon. Ordered to examination for promotion. February 14, 1894.

STIMPSON, W. G., assistant surgeon. Ordered to examination for promotion. February 14, 1894.

BROWN, B. W., assistant surgeon. Ordered to examination for promotion. February 14, 1894.

ROSENAU, M. J., assistant surgeon. Granted leave of absence for thirty days. February 26, 1894.

COFER, L. E., assistant surgeon. To proceed to Mobile, Ala., for duty. January 30, 1894.

EAGER, J. M., assistant surgeon. Granted leave of absence for four days. January 30, 1894.

BLUE, RUFERT, assistant surgeon. Granted leave of absence for eight days. January 26, 1894.

NORMAN, SEATON, assistant surgeon. Ordered to examination for promotion. February 14, 1894.

PROCHAZKA, EMIL, assistant surgeon. To proceed to New York, N. Y., for duty. January 24, 1894. To proceed to Buffalo, N. Y., for temporary duty. February 2, 1894.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held at 19 Boylston Place, on Monday, March 5th, at 8 o'clock.

Readers: Dr. J. S. Greene: "The Obscure Origin and Indeterminate Course of Acute Infection, as Illustrated by a Case, Possibly of Multiple Neuritis, and by a Case of Malignant Endocarditis."

Dr. E. M. Greene: "Crystalline Deposits in the Urine; Their Occurrence and Significance."

Report of Treasurer.

Report of Committee on Admissions.

Appointment of committee to nominate officers for ensuing year.

JOHN C. MUNRO, M.D., Secretary.

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — The Surgical Section of the Suffolk District Medical Society will hold its regular monthly meeting at 19 Boylston Place on Wednesday evening, March 7, 1894, at 8 o'clock.

The subject for discussion will be introduced by Dr. J. W. Elliot: "A Gall-Stone Removed by Opening the Common Bile Duct, the Wound in the Duct being Closed by Sutures."

Dr. G. W. Gay, R. H. Fitz, C. B. Porter, H. L. Burrell, J. C. Warren, A. T. Cabot, M. H. Richardson and W. M. Conant will briefly discuss the "Surgery of the Gall-Bladder."

CHARLES L. SOUDDER, M.D., Secretary, 1 Marlborough St.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday evening, March 7th, at 8 o'clock, by Dr. John Homans. Subject, "Ovariectomy." Physicians are cordially invited.

ERRATUM.

In the note on the hearings of the Public Health Committee in last week's issue of the JOURNAL, the date for the hearing on public vaccination should be March 7th instead of March 5th as given.

RECENT DEATHS.

BENJAMIN STORER CODMAN, M.D., M.M.S.S., died in Boston, February 22d, aged seventy-eight years. He graduated from the Harvard Medical School in 1845. In 1855 he retired from practice and established the firm of Codman & Shurtleff, dealing in surgical instruments. He was a trustee of the Home for Intemperate Women.

DR. GUSTAV SCHENTHAUER, Professor of pathological anatomy in the University of Pesh, died January 28th.

BOOKS AND PAMPHLETS RECEIVED.

The Absorption of Immature Cataract, with Restoration of Vision. By J. Hobart Egbert, A.M., M.D., Ph.D. Reprint. 1893.

The Surgery of the Hand. Sarcoma of the Kidney; Its Operative Treatment. By Robert Abbe, M.D., of New York. Reprints. 1894.

A Human Embryo of the Second Week. Early Human Embryos and the Mode of their Preservation. By Franklin P. Mall. Reprints. 1893.

Proceedings of the Philadelphia County Medical Society. Volume XIV, Session of 1893. Lewis H. Adler, Jr., M.D., Editor. Philadelphia: Printed for the Society. 1893.

The Present Status of the Treatment of Uterine Fibroids. Etiology of Pelvic Diseases in Women and their Prophylaxis. By X. O. Werder, M.D., Pittsburgh, Pa. Reprints. 1893.

Antiseptic Therapeutics. By Dr. E. Z. Trouessart, Paris, France. Translated by E. P. Hurd, M.D. Two volumes. The Physicians' Leisure Library. Detroit: George S. Davis. 1893.

A Text-book of the Theory and Practice of Medicine. By American Teachers. Edited by William Pepper, M.D., LL.D., Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania. In two volumes. Illustrated. Volume II. Philadelphia: W. B. Saunders. 1894.

Holden's Manual of the Dissection of the Human Body. Edited by John Langton, Surgeon to, and Lecturer on Anatomy at St. Bartholomew's Hospital; Member of the Board of Examiners, Royal College of Surgeons of England, etc. Sixth edition. Revised by A. Hewson, M.D., Demonstrator of Anatomy, Jefferson Medical College, etc. Three hundred and eleven illustrations. Philadelphia: P. Blakiston, Son & Co. 1894.

Original Articles.

OBSERVATIONS ON PNEUMONIA.¹

BY WILLIAM H. PRESCOTT, M.D.

ACUTE FIBRINOUS PNEUMONIA WITH UNUSUAL EXTENSION OF THE FIBRINOUS EXUDATION.

THERE is nothing of especial importance in the clinical history of this case. The patient, a man about thirty-five years old, was brought into the hospital with well-marked evidences of pneumonia. There was complete consolidation of the lower half of the left lung and slight breathing, with less well-marked consolidation in the lower posterior portion of right lung. The temperature was high, and the breathing very much accelerated. The condition of the patient steadily grew worse, and he died forty-eight hours after entry into the hospital.

The autopsy was made November 25th, twenty-four hours after death. The body is that of a slightly built man. The mucous membrane pale, rigor mortis well developed. The superficial veins over chest prominent. The face cyanotic.

Scalp slightly adherent. Dura mater of ordinary thickness. Pacchionian granulations well developed. The pia slightly cloudy. The convolutions of brain well marked. Brain slightly oedematous.

Subcutaneous fat slight in amount. Muscles red. Peritoneal cavity moist. The appendix bound down by old adhesions extending across from the ileum. These adhesions involved the proximal two-thirds of the length of the appendix, leaving the tip free. The peritoneum over appendix thickened. Diaphragm on right side at lower border of fifth rib; on left side, in fifth intercostal space.

In the left pleural cavity about 500 cc. of cloudy serum containing flakes of fibrin. Both cavities free from old adhesions. Lungs do not retract on removal of sternum. The precordial space small. On the anterior surface, especially over the upper two-thirds, there is a thick fibrinous deposit on the epi-pericardial tissues. The pericardial cavity is obliterated over the anterior upper portion by fresh, thick fibrinous adhesions. In the lower portion of the cavity there is a small amount of clear fluid. The visceral pericardium in its upper portion, extending especially over the root of the aorta, is covered with a thick fibrinous exudation, containing here and there small hæmorrhages. The myocardium is generally pale. Immediately beneath the pericardium where the exudation is thickest the tissue is somewhat opaque and contains small hæmorrhages.

The heart of ordinary size. On the right segment of the mitral valve near its attachment, there is a minute superficial erosion not more than one millimetre in extent, covered with a thin, granular, hæmorrhagic fibrinous deposit.

Over the entire pleural surface of the left lung there is a thin fibrinous exudation, and in the pleura beneath it there are numerous small hæmorrhages. Over other portions of the pleura the exudation is thick and yellowish, and is easily removed as an adherent membrane, leaving the underlying pleura cloudy. The upper lobe of this lung is hyperæmic, oedematous, and more solid than normal. On pressure much

blood-stained serum can be squeezed from the cut surface, and thick purulent exudation from the bronchi. The upper and lower lobes united by fresh adhesions. Fully two-thirds of the lower lobe is completely solid. The cut surface of this is gray, granular, and on pressure pus can be squeezed from the bronchi. The remainder of the lobe is intensely congested and partially solidified. Portions of the lobe will float in water. The costal pleura on the left side is covered with a thick fibrinous exudation. On being stripped off the vessels in it are enormously dilated, and hæmorrhages have occurred everywhere in the tissues. The intercostal muscle, especially in the upper half of the pleural cavity, appears swollen and softened. On section the intercostal muscle and subpleural tissues are thickened by an exudation which is intimately associated with the tissues. This exudation in places appears to extend through the entire thickness of the intercostal muscle, and there is apparently a sharp line separating it from the healthy tissues. At the apex of the pleural cavity a similar condition exists, and extends from here into the posterior mediastinum, and into the cervical regions. Some of the deep-lying cervical lymph-glands are reddened and swollen, and around them this fibrinous exudation is seen. In one place in the epi-pericardial fat there is a small collection of thick, creamy, gelatinous pus. The right lung is voluminous. The pleura smooth and free from fibrinous deposit. On section the lung is in general hyperæmic and oedematous. In the lower lobe there are scattered foci of consolidation varying in size from one to five centimetres. Pus can be squeezed from the bronchi in these places.

Liver is large. The surface pale. On section cloudy and opaque with indistinct lobules. The bile-duct free. The gall-bladder contains clear, yellowish bile.

The kidneys somewhat enlarged. Capsule easily stripped off. Surface smooth. On section, markings somewhat obscure. Cortex swollen and opaque. Glomeruli anæmic.

The spleen slightly enlarged. The capsule wrinkled. On section rather soft and dark. Neither trabeculae nor Malpighian bodies are visible. The adrenal glands and pancreas normal. The mucous membrane of stomach and intestines is hyperæmic, otherwise normal.

The mucous membrane of larynx and trachea is congested. Beginning in the lower part of the larynx and continuing uniformly through the trachea as far as the bifurcation, the mucous membrane has a granular appearance due to the presence of small vesicular-looking granules, of regular size, on the surface. This does not disappear on washing, but on gently rubbing the granules disappear and a thick fluid takes their place. This condition is due to small masses of the mucus distending the glands. The aorta and other arteries are normal.

ANATOMICAL DIAGNOSIS.

Acute fibrinous pneumonia with consolidation of lower lobe of left lung. Slight consolidation in upper lobe of left lung. Fibrinous lobular pneumonia of right lung. Acute fibrinous pleurisy of left pleura with extension of the process into the chest walls and into the posterior mediastinum. Acute fibrinous pericarditis with extension into myocardium. Acute endocarditis of mitral valve. Acute parenchymatous degeneration of liver, heart, and kidneys with slight fatty degeneration.

¹ A contribution to the forthcoming Medical and Surgical Report of the Boston City Hospital, from the Pathological Department of the Hospital, under direction of Dr. W. T. Councilman.

Cover-slips made from the lung, from the fibrinous exudation on the surface of the pleura and from the pericardium, showed large numbers of the diplococcus lanceolatus with well-marked capsule staining. In the fresh sections of the intercostal muscles the same condition was found. Fresh sections of the kidney showed swollen and granular epithelium in the convoluted tubules, with here and there minute drops of fat on the addition of acetic acid. The glomeruli were unchanged. Sections of the liver showed swelling and granular degeneration of the hepatic cells. Sections of heart showed a very slight fatty degeneration of the muscle. Portions of the various tissues were hardened in alcohol for further examination.

Microscopic examination of the consolidated portion of left lung. The alveoli are everywhere distended with fibrin and pus cells. Numbers of diplococci were found in the pus cells. Sections made from the less consolidated portions of this lung and from the areas in the right lung show a less advanced process. The vessels in the alveolar walls are dilated, and the walls themselves infiltrated with leucocytes. Within the alveoli there are small amounts of fibrin with numerous red and white corpuscles.

The most interesting conditions were found in the pericardium and in the pleura. The fibrinous exudation of the pericardium is very dense, and the fibrin is in places in the form of large, broad fibres which are frequently united together to form hyaline masses and a reticulum, somewhat similar to that in the diphtheritic membrane. In places it extends into the tissue of the myocardium. In these places there are numerous leucocytes, round and epithelioid cells between the muscular fibres. The muscular fibres appear swollen, and the nuclei are indistinct. In the least affected part of the myocardium there are no leucocytes in the tissue, but there are numbers of large epithelioid cells and round granulation cells between the muscular fibres. In these places there is no fibrin, and the muscular fibres themselves appear to be but little altered. Further back in the more affected portions the leucocytes are found, and with these masses of fibrin. Diplococci were found in great numbers in the exudation, both inclosed in the pus cells and scattered through the fibrin. None were found where the tissue contained only the epithelioid and round cells.

The process appears to invade the fat in the same way. In places, as observed with the low power, the fibrinous exudation and the leucocytes extend directly into the fat, passing along the connective-tissue septa.

On examination with a higher power, in the areas of fat, which under the low power appeared to be unchanged, there is a similar condition to that found in the myocardium. There are numerous large epithelioid cells between the fat cells, of the same character as those found in the myocardium. The fat vesicles themselves appear to be somewhat compressed and distorted by the formation of cells between them, but are otherwise unchanged. In some places only one or two of these larger cells were found, and in others they are more numerous. The inflammatory process appears to extend into the tissue along the lymphatics and blood-vessels. In one place a longitudinal section of a capillary is seen, the nuclei of which are swollen and granular, and the lymph sheaths of the larger blood-vessels are completely filled up with these large granular cells.

Examination of the intercostal muscle shows a

similar condition. The fibrinous exudation with leucocytes extends into this, generally in the form of large bands in the intermuscular septa. There is also an extension in the muscle nearest the pleura between the individual muscular fibres. In the most affected places the muscular fibres are swollen, granular and necrotic; the nuclei do not stain, and they have lost the cross striation. In advance of the fibrinous exudation with leucocytes, there is simply a cellular infiltration without either fibrin or leucocytes. The cells in this are almost all of them large epithelioid cells with a clear, brightly staining nucleus. In one or two places nuclear figures were found in these large cells. Diplococci were only found associated with the presence of the leucocytes and fibrin.

A rabbit was inoculated from the fibrinous exudation in the intercostal muscles, a small portion of the muscle being placed beneath the skin of the back of the animal. An acute swelling developed at this place, but there was no distinct abscess formation. The animal in the course of the next few days lost some flesh, but it continued to eat comparatively well until it was killed, ten days after the inoculation. There was a large subcutaneous swelling at the point of inoculation, which had extended from this in all directions, especially downwards on the side where the inoculation was made. The entire subcutaneous tissue of the abdomen was swollen and infiltrated with a dense fibrinous exudation. Here and there in this exudation were softer places from which a thick tenacious pus could be squeezed. The tissue in places was one cubic millimetre in thickness. The inguinal and axillary lymph-glands on the side of the inoculation were reddened and swollen. No bacteria were found, either in the purulent portions or in the fibrinous masses, neither on the direct examination of cover-slips nor in the cultures which were made, both from the seat of the inoculation and from all the internal organs.

This case is interesting on account of its unusual extension. Practically in all cases of acute fibrinous pneumonia there is a similar fibrinous exudation on the pleura covering the affected portion of the lung, to that in the lung itself. In most cases the fibrinous exudation is not confined to the pleura immediately over the affected portion of the lung, but extends from this over the entire surface. There will usually be found a similar condition on the costal pleura, but not so marked as on the visceral. An extension of the process into the chest walls and into the mediastinal tissues from the pleura is exceedingly rare.

In this case there is no question but that the process in the chest walls is one of direct extension from the pleura. The histological examination of the tissues here was of great interest. Apparently the first change which took place in the intercostal muscle, in the myocardium, and in the fat of the pericardium was a cellular proliferation of the interstitial tissue. The new formation of cells appeared to have taken place from the interstitial tissue, most probably from the cells of the capillary walls or from the lymph spaces. The newly-formed cells were of two sorts. There were large cells with an abundant protoplasm and a large brightly staining nucleus, and small cells similar to the lymphoid corpuscles of the blood, with a nucleus almost filling up the body of the cell. In this tissue there were no leucocytes nor fibrin. They appear to come later, and with the leucocytes and the fibrin the organisms were always found.

ACUTE INFECTION WITH THE DIPLOCOCCUS LANCEOLATUS IN A CHILD FIFTY-SIX HOURS OLD, THE INFECTION PROBABLY TAKING PLACE AT TIME OF DELIVERY.

I am indebted to Mr. J. R. Poor, of the Harvard Medical School, for the autopsy and for the history of his case.

The mother of the child was a primipara, belonging to the criminal class. Two months before delivery an abscess of the breast had developed, following on a sick. At the time of delivery this was completely healed, leaving a stellate cicatrix. The mother was a healthy young Irish woman. Since delivery the mother has done well, with the exception of a very slight rise of temperature on the third day, apparently due to a family row. There was no respiratory trouble whatever. The birth took place at noon, May 12th. The delivery was a somewhat slow one, necessitating the application of forceps. The child was slightly asphyxiated at time of birth. The respiration was rather slow, necessitating hot and cold applications. No trouble noticed in the child until the 14th, forty-eight hours after delivery: then it appeared to be rather dull and slightly cyanosed. It died suddenly at seven P. M., fifty-six hours after delivery. Before death vomited slightly.

Autopsy made twelve hours after death. Male child, large and well formed. Posterior to the right ear there is a large ecchymosis made by forceps. A very slight hæmorrhage in the dura, on the right side, corresponding to the external ecchymosis. The brain is normal. In the peritoneal cavity there is a small blood-clot. No adhesions. In the anterior mediastinum there is a slight amount of hæmorrhage, the thymus glands being especially infiltrated with blood. In each pleural cavity there is a slight amount of hæmorrhagic exudation. The pleural surface of the right lung over the lower lobe shows in places a fine fibrinous exudation. The entire lower lobe of the right lung completely consolidated. The lower portion of the upper lobe also consolidated. The pleural surface of the lung sprinkled with fine ecchymoses. The consolidated lung is of a dark-red color, looking somewhat like a hæmorrhagic infarction. On section it is dark red. The cut surface is dry and smooth. The granular appearance of an ordinary croupous pneumonia is absent, but the lung is not so smooth as it would be in a purulent or hæmorrhagic consolidation. The bronchi contained bloody mucus. The left lung shows almost the same condition as the right. Consolidation complete in the lower lobe and in a considerable portion of the upper. In the pericardial cavity there is a considerable quantity of slightly opaque serum. The visceral pericardium sprinkled with small hæmorrhages, which are also seen in the myocardium.

The valves of the heart normal. The ecchymoses are not only found in the pericardium, but extend from this into the muscular tissue of the heart, and especially into the intraventricular septum. In the trachea there is a quantity of blood-stained mucus. The pharynx and œsophagus are normal. In the stomach there is a considerable amount of dark blood. The liver large, rather pale, and on section there are numbers of opaque, slightly reddish foci of an average size of half a millimetre, which contrast sharply with the surrounding parenchyma. The spleen is large. On section homogeneous, rather soft. Neither Malpighian

bodies nor trabeculae are visible. No abnormal condition found in the other organs.

Cover-slips examined, made from the lungs, show enormous numbers of typical diplococci with well-defined capsules. Similar organisms were found in the blood from the heart, and in the scrapings from the other organs. Cultures made from the organs gave pure cultures of diplococci from the lungs, heart, blood, liver, spleen and kidneys.

A rabbit inoculated with scrapings from the consolidated lung died in three days of typical diplococcus septicæmia.

Examination of the consolidated portions of the lung showed an absence of typical appearance of fibrinous pneumonia. The consolidation was almost entirely due to hæmorrhage into the lung. In places there were small amounts of fibrin. Usually this was mingled with the red corpuscles, but in some places it was found in the alveoli almost alone. Here and there a few leucocytes were found along with the red corpuscles, but the numbers of these were exceedingly scanty. There was everywhere hyperæmia of the vessels, and as far as could be ascertained by the examination of the cross-sections of the larger vessels, there was no leucocytosis. In many portions of the lung the appearance resembled that of the foetal lung. The mucous membrane of the bronchi in these places was convoluted and the alveoli imperfectly expanded. Diplococci were everywhere present in enormous numbers. They were found not only in the hæmorrhagic exudation within the alveoli, but were also present in the alveolar walls and in the cross-sections of the larger blood-vessels. Fresh sections made of the various organs at the time of the autopsy showed no abnormal condition.

This case is of especial interest from the early age of the child, and the character of the infection produced by the diplococcus lanceolatus. In this case there was a general infection of the entire organism, similar to that which is usually produced in rabbits by inoculation with virulent cultures of the diplococcus. In spite of the early age of the child, it is not at all probable that the infection took place in utero. The mother was absolutely free from pneumonia or from any other pathological condition at the time of birth.

Welch has gone over carefully, in his paper on the diplococcus lanceolatus, all of the cases which have been reported of intra-uterine infection of the fœtus. In most of these cases death of the infant has taken place two to five days after birth; and although the infection was probably intra-uterine, the possibility of this having taken place during or after birth cannot be absolutely excluded. The most satisfactory of these cases is that reported by Birch-Hirschfeld. On the fourth day of a fibrinous pneumonia, the mother gave birth to a seven-months' still-born fœtus with intact membrane. There were hæmorrhages in the maternal and middle parts of the placenta. The only lesion noticed in the fœtus was ecchymosis in the pelvis of the kidney. Typical diplococci were found by culture in the liver, heart's blood, and umbilical vein.

It is well known that acute fibrinous pneumonia developing during pregnancy is likely to bring about miscarriage. This is the case not only in human beings, but in mice and rabbits which have been inoculated.

The character of the exudation in the lungs was also of interest. The exudation in the lungs was to a

large extent hæmorrhagic in character, and the condition most resembling that produced by the organisms in the adult was the fibrinous exudation on the pleura. There can be little doubt from the extent of the lesions in the lung that the organisms had entered the lungs first, and probably at the time of birth. The artificial respiration carried on may have been responsible for the entry of the organisms into the lungs.

The two cases also show a marked contrast, not only in the character of the lesions in the human cases, but also in the character of the lesions produced in the animals. In the first case there was a marked tendency to a local extension of the organism, with the production of a typical fibrinous exudation wherever it was found. The same thing was seen in the rabbit which was inoculated with the exudation.

These varying effects which are produced by inoculation with the diplococcus lanceolatus are probably to be referred to especial differences in the action of the organisms, and not to a mere difference in the degree of virulence. Cultures of the pneumococcus are sometimes met with which will always produce in every generation the same definite lesions.

CASES OF APPENDICITIS PRESENTING UNUSUAL FEATURES.¹

BY MAURICE H. RICHARDSON, M.D.

ACUTE CASES.

THE following unusual cases of appendicitis have been selected from those under my care in the past four weeks. They are reported in detail because each presents some variation from the ordinary case, and because in the existing uncertainties as to etiology, pathology and treatment, every observer owes to workers elsewhere a faithful report of his cases, whether successful or unsuccessful. There are many points of interest in regard to which these cases are too recent for deductions of value; in certain other respects, however, they justify definite conclusions.

I. Fulminating peritonitis: removal of gangrenous but unperforated appendix on second day; death. (Specimen.)

In a recent paper on appendicitis² I stated that in all severe acute cases with marked general and local symptoms, every appendix which I had removed was found to be perforated; and that in my belief the first symptoms depended upon such perforation. This opinion, though based upon a careful observation of many cases, is open to the criticism of being too strongly expressed. I hasten to report, therefore, an exception to this statement—a fatal fulminating case in which no perforation could be found on the most careful examination. The following are extracts from short-hand notes:

"Benjamin J. S., aged thirty-eight, single, East Boston. Dr. O'Keefe. Thursday, December 21, 1893. The previous health has been good. He was ruptured ten years ago. He has already had five attacks similar to the present. The last one occurred a year ago, keeping him from his business four or five days. Night before last he first began to feel a little pain in the bowels. Nevertheless, yesterday he was up and about

till towards night. The symptoms had by that time increased so much that he had to go to bed, where he passed a restless and sleepless night. There was no vomiting. This morning he had a chill. All this afternoon the pain has been persistently located in the right flank, and has been growing worse. He fixed the seat of pain at first in the centre of the abdomen (indicating the median line just above the pubes). This morning it was half-way between the umbilicus and the anterior superior spine of the ileum. The pulse this morning was 80; the skin cool. He has vomited two or three times to-day. He has passed some gas, but not much.

"*Physical Examination.*—He is in a state of moderate shock. The general appearance is bad; he lies in bed restless and groaning. The pulse is 112, weak; the temperature 100°. The extremities are cool. The very rigid abdomen is dull over the bladder; elsewhere resonant. There is general tenderness, with constant eructations of gas. By the stethoscope no intestinal sounds can be heard. Though assured that the case is practically hopeless, his friends wish him to go to the hospital."

I sent an ambulance immediately, and an operation was performed by Dr. Newell in about two hours from this time. A thick and short appendix was removed, the tip of which was gangrenous. There was free fluid in the abdominal cavity. The intestines were congested and paralyzed. The appendix was tied and removed; the abdomen irrigated. No cultures were made. The patient gradually sank, and died at one o'clock Saturday morning.

The general condition of collapse, the rigid and distended abdomen, made the prognosis in this case nearly hopeless. I had predicted confidently a gangrenous and perforated appendix, with general infection. The general infection and gangrenous appendix were found, but no microscopic or macroscopic perforation could be detected. Though no cultures were taken, there is little doubt that an escape of micro-organisms from the appendix had taken place through the patch of gangrenous tissue. The absence of perforation in this instance is the feature which I wish to emphasize. I had never met with just this condition of the appendix before. It would seem that in general infection perforation does not necessarily exist. Not that this observation detracts in any way from the importance of the early interference in cases of this kind. Whatever the pathological condition of the appendix may be, the escape of its micro-organisms into the peritoneal cavity, whether through a large opening or through a small one, or by gradual march through the lymph spaces, places the patient in the utmost jeopardy. Excision of the organ, with drainage and irrigation, should be performed at the earliest possible moment in every such case.

II. Appendicitis of three weeks' duration; large abscess in pelvis; complete intestinal obstruction; fecal vomiting; operation; relief of obstruction; death in six hours.

This patient presented the unusual complication of acute obstruction. There was no doubt upon this point, for the intestinal contractions, seen through the thin abdominal walls, were accompanied by loud borborygmi and intense pain. The patient was very much reduced in strength, and was already regurgitating the contents of the upper bowel.

"George T. B., aged twenty-one, South Hanover,

¹ Read by title before the Boston Society for Medical Improvement, January 8, 1894.

² American Journal of Medical Sciences, January, 1894.

Mass. Friday, December 22, 1893. Drs. Charles and McMillan.

"About four weeks ago he had a slight attack of appendicitis, with localized pain and tenderness. He described his pain as 'across his bowels.' Later, it was in the right iliac region. The pain subsided, and he began to improve, so that he got up and went about the house. Then the pain came on again. After two or three days he got better, and was not seen by Dr. Charles till last Monday. On that day he said that he had the pain only once in a while. In the beginning there was a temperature of 101°. Last Friday he had an attack like gastralgia, with pain in the epigastric region. This soon subsided, and has not been a prominent symptom since. There have been no chills. He gave a history of two previous attacks. The first one lasted but one day. The pain at that time was in the same place, 'across the bowels,' 'across the pit of the stomach.' Repeated questioning as to the locality of the pain elicited the same answer; 'right across the bowels.' The vomiting began last Saturday afternoon, and has continued ever since.

"*Physical Examination.*—Pulse 116, temperature normal. At times during the examination he complained of violent colic. Accompanying the pain, spasmodic intestinal contractions could be seen through the thin abdominal wall. Rectal examination showed a large tumor pressing on the bladder and apparently filling the whole pelvis. In this tumor irregularities in consistency could be felt, so that the question of draining by rectum was considered. The existence of acute obstruction decided me to select the incision through the median line.

"*Operation.*—A median cut was made between the umbilicus and the pubes. An acute obstruction of the bowels was found, caused by an omental band. The small intestine above the obstruction was dark-red in color and excessively distended. Deep in the pelvis filled with foul pus, was a large abscess cavity, the adhesions of which were separated with great difficulty. After cutting the band the cavity of the pelvis was washed out with peroxide of hydrogen, packed with gauze, and drained by means of a rubber tube. The operation was very rapid, not lasting more than twenty minutes. The patient died on the following morning."

This case is very similar to that of Mrs. C. F. A., reported last year,* in which recovery was due undoubtedly to a spontaneous opening in the cœcum through the stump of the appendix. In the present instance the coils of small intestine were bound down in the pelvis, and were relieved with great difficulty. There was no apparent hypertrophy of the intestinal wall, though its lumen was dilated and its peritoneum darkly congested.

The question of relieving the obstruction by opening the gut is interesting in these conditions. There is reason for supposing that such relief would have been attended by less risk than the methods used; yet the chief trouble would have remained untouched by a simple enterotomy. Moreover, the opening must have been made in the small intestine, possibly so high up as to interfere with nutrition. It seemed better, therefore, after thorough exploration, to remove at once the cause of obstruction. The immediate cause of death was the shock caused by manipulations upon the abscess, though they were extremely brief. The contents of the abscess cavity soiled the adjacent coils

of intestine. They were immediately disinfected as thoroughly as possible by means of peroxide of hydrogen. Even if the bowel had been opened after separating the adhesions about the appendix, it is not likely that recovery would have followed. A rapid enterotomy alone might possibly have tided the patient over the crisis until strength enough could be stored to enable him to undergo even the slight manipulations of drainage.

III. Appendicitis; apparent general peritoneal infection; mechanical obstruction; removal of perforated and gangrenous appendix; drainage; recovery. Peritoneal exudate sterile; colon bacillus in appendix. Recurrence of obstruction in four weeks. (Specimen.)

This case is the only one in my experience in which I have demonstrated satisfactorily an acute mechanical obstruction in the first days of an appendicitis. That the obstruction would have continued cannot be asserted; yet it was sufficient to cause unmistakable fecal vomiting, and was immediately relieved by separating the adhesions by which the small intestine was glued into the vesico-rectal fold by inflammatory adhesions.

"Binney, L. H., twenty-four years old, cabinet-maker. Thursday, December 28, 1893. Dr. Stevens of Cambridge.

"Last Sunday afternoon he first had pain in the belly, which he tried to relieve by walking. He walked around for a long time without relief. The pain continued two days. Wednesday morning it became intense and Dr. Stevens was called.

"*Dr. Stevens.*—'When I came he had a great deal of pain in the abdomen, a pulse of 72, and a temperature of 99°. His hands and feet were cold. His abdomen was flat, retracted, rigid, and tender; more tender on the right than on the left, from the pubes round to the right side. It acted like a perforation of the appendix. He was in a state of collapse, and it did not seem wise to interfere until he should rally. At five o'clock that afternoon he had rallied. Temperature 103°, pulse 110. He was pretty free from pain. At eleven o'clock, Wednesday night the temperature was 101°, pulse under 100. No vomiting. On Sunday night he had a chill. There was a little nausea, but no vomiting. On Monday he took a cathartic. This (Thursday) morning the temperature was 100° and the pulse 76. There was no vomiting. He could not pass his urine. The abdomen was slightly tympanitic. The muscles were extremely rigid, especially on the right side; and he had a pretty sick look. He has gone on through the day in about the same condition. At the present time (8.45 P. M.) he is in great pain. He has never had anything like this before.'

"*Patient's Statement.*—'I was taken Sunday about four o'clock. It was a good deal like a stomach-ache, and yet it was not. The pain was right across my stomach and my bowels, here (indicating the region of the bladder). The pain now is in the same place as at first. The attack was preceded by a diarrhoea following the use of rhubarb.'

"*Physical Examination.*—Pulse 72 to 80, temperature 99.8°. Complains much and groans constantly. Very tender on both sides in the lower part of the abdomen. There is some general tenderness without rigidity. No tumor; no dulness. Rectal examination negative.

"Friday, December 29, 1893, 10.20 A. M. Pulse 70, temperature normal. The abdomen is distended,

* Ten Days of Appendicitis, Boston Medical and Surgical Journal.

and tender in the lower portion, where he complains also of pain. No sounds can be heard by stethoscope. The vomiting is distinctly fecal in odor and color."

Dr. Taylor, of Cambridge, was present at this examination; also Dr. C. A. Porter, of Boston. It was a question, first, of appendicitis; secondly, of a general peritoneal infection; and, finally, of an acute obstruction. It seemed to me most like an acute intestinal obstruction. A grave prognosis was given.

An incision several inches in length was made in the right linea semilunaris. On nicking the peritoneum slightly cloudy serum escaped, from which a culture was immediately taken. The cœcum was found collapsed: the last three inches of the ileum were empty and flattened. The small intestines presenting were very much distended. The peritoneum was nearly normal, but slightly injected. The free fluid in the peritoneal cavity was removed as well as possible by means of dry sterile gauze. Adhesions could be felt about the appendix, which was situated in the pelvis between the rectum and the bladder. Gauze barriers were suitably placed to protect the general cavity of the abdomen before separating the adhesions, about which a small amount of fecal pus was found. The parts about the abscess were irrigated freely with peroxide of hydrogen. The lowest segment of the ileum was caught at a sharp angle deep in the pelvis among the adhesions about the appendix. Above this angle there was great distention; below, collapse. After the adhesions had been separated and this portion of the bowel delivered, gas at once filled and distended the cœcum.

The recovery of the patient seemed very doubtful; yet he rallied, and is now well. Vomiting continued two or three days, and was treated by absolute rest to the stomach and intestines, neither food nor cathartics being given. At the end of three days the bowels began to move, the vomiting ceased, and the patient became convalescent.

It has been said in reference to this case, that the obstructions described frequently exist in acute general peritonitis. A general infection was thought to be present at the time, though the appearances did not indicate a general peritonitis. Moreover, it must have been an inflammation independent of micro-organisms, or, at least, of those which grow upon the medium of blood-serum, for to this day the tube inoculated from the fluids free in the abdominal cavity remains sterile, though from the appendix itself abundant growths of a large, thick bacillus have developed. Furthermore, that the obstruction was not due to a paralysis of the intestine was shown by the existing borborygmi.

In this case the sterility of the free fluid is a fact of the greatest interest, and it explains the rapid recovery. In many instances a fluid apparently precisely similar has shown a rapidly growing microbe. In such cases death has invariably followed.

IV. Probable appendicitis at the age of seventy-eight; no operation; recovery.

The following case seems worth recording in detail, because it presents the typical history of appendicitis at a very advanced age.

"Andrew H., aged seventy-eight, North Hanover, Mass. Thursday, December 21, 1892. With Dr. McMillan.

"Night before last his trouble began with severe pain in the right side. He was cold and pallid. For many years he had been ruptured on both sides. There

was no indication of any strangulation or incarceration; there was no protrusion at the rings. The first symptom day before yesterday was vomiting, which lasted about ten minutes, and was followed by pain which ceased yesterday. He had two movements of the bowels from oil and enema. He never had anything like this before. The temperature last night was 103°; this morning it is 101°. The pulse was 104; now 90. His general appearance was good. There is tenderness in the right side of the abdomen, near the crest of the ileum, where there is also resistance and dullness. The temperature night before last was 103°. The right side was hard and tender." The condition of pyrexia in this case continued a few days. The symptoms gradually subsided, and the man is now well.

The history of this case is precisely like that of appendicitis with localized peritonitis. It is very unusual to see an appendicitis at this age. In one instance I have found, at the autopsy, in a woman of about seventy, a gangrenous and perforated appendix containing a gall-stone. If this man had been younger, or if there had been evidence of an abscess in the right iliac fossa, I should have advised interference. The patient was very much opposed to operation, preferring to die.

V. Appendicitis complicated by bronchitis; removal of appendix slightly affected; pneumonia; empyema; thoracotomy and excision of rib; recovery.

On Wednesday, June 7, 1893, I saw in East Boston, with Dr. Morrison, Fred A. R., aged six, who was taken sick the previous Saturday morning, complaining of pain in the side. (The father indicates the right lumbar region.) He had a good deal of pain, with some vomiting. He could keep nothing on his stomach. Sunday he was the same, complaining also of headache. On that day he was seen by a physician. Vomiting continued during Monday. Last night he was first seen by Dr. Morrison, who found him with a temperature of 104.5°. There was no symptom except this pain in the right iliac region, just between the umbilicus and the anterior spine. The left side of the abdomen was also tender. This morning he had rather more pain than last night, but there has been no vomiting since day before yesterday.

Physical Examination.—Pulse 120, respiration 40, temperature 102°. Though the abdomen was generally distended and tender, the tenderness was especially marked in the region of the appendix. There was no tumor; the tongue was clean. The thighs were flexed. The respiration was noisy and rattling; the cheeks were flushed; the eyes sunken. The general appearance was bad. There seemed very little doubt that this boy was suffering from an acute inflammation of the appendix, with perforation and a more or less general infection. The respiration of the left chest indicated trouble there, probably pneumonia. (This proved to be the case.) The surroundings of this child were so bad that we decided to send him to the hospital. The history and physical examination of this boy pointed clearly to appendicitis. On arrival at the hospital he was seen by Dr. Beach, who confirmed the diagnosis and opened the abdomen. The appendix was removed and found apparently normal. The child rapidly developed a pneumonia, from which he recovered. The abdominal wound healed firmly, and he soon became convalescent. This patient, in July, while under my care, developed an empyema on the right side, for which a rib was resected and drainage applied. The boy recovered rapidly from this op-

eration, gained very much in weight and strength, and was discharged from the hospital a picture of health, in spite of the fact that tubercle bacilli were found in the sputum.

I am informed by Dr. Beach that after removal of the appendix, on careful examination a condition of thickening and of catarrhal inflammation was found. That this condition of the appendix was not the cause of the acuteness of the symptoms, seems to me very certain, for the general pain and tenderness, with the rigidity of the abdomen and the flexion of the thighs, mean gangrene and perforation, or at least a septic extravasation, if any value at all can be placed upon this combination of signs.

Very similar to the last case is the following which I saw in consultation with Dr. Berlin on January 1, 1894. Had it not been for the experience gained in the above instance I should have said that this, too, was an acute inflammation of the appendix, complicating a pneumonia, and possibly I should have advised exploration. I certainly should have done so, had I adopted the rule to operate upon every case of appendicitis as soon as the diagnosis was made.

VI. Pneumonia apparently complicated by appendicitis; no operation; recovery.

Malcolm E., aged four, January 1, 1894.

"Always delicate. Two years ago had whooping-cough, after which he went South for the winter. Last Thursday, the 20th, he said he had a stomach-ache. The abdomen was flat. The only symptom was pain. At one time he would complain of the right side, and at another of the left. The symptoms were not alarming. The temperature was 101°, the bowels free. On Friday, there was evidence of trouble in one of the lungs, thought to be pneumonia. There was no local abdominal tenderness. On Saturday the temperature reached 105°, and he said his stomach hurt him. He complains of a good deal of pain in the abdomen (indicating the epigastrium). This morning he locates the pain in the right side all the time."

The cheeks were red and the respiration was rapid, though not labored. The abdomen was somewhat prominent, but not rigid. Intestinal sounds could be heard with the stethoscope. There was no dulness. Pulse 120, temperature 102.2°. Tenderness more or less general.

The complaints of this child, with the physical signs, obscure though they were, would have been strongly suggestive of an acute appendicitis, had it not been for the experience gained in the preceding case. The evidence in this case, however, is much less indicative of an appendicular trouble than that in the former. In children and young males persistent pain in the abdomen, of whatever nature, even if far removed from the usual seat of the appendix, is usually dependent upon an inflammation of that organ. The errors to which we are liable are not in the direction of early interference or mistaken diagnosis; they depend rather upon our overlooking the lesion and delaying its appropriate treatment. For one instance in which the interference has been useless or too hasty, I could point out a large number in which failure to appreciate early the gravity of the case has been followed by a fatal termination.

Abdominal symptoms occurring in the course of acute thoracic diseases are not unknown. Dr. Russell Sturgis writes me in regard to this as follows: "I have several times been able to confirm the observa-

tions of Dr. Eustace Smith, made in 1876, that the pain of pleurisy in children is frequently referred to the belly, and I have noticed abdominal pains as not of infrequent occurrence in the pneumonias of children. Dr. Smith thinks that the reference of pain to the belly is due to implication of the lower intercostal nerves, the ends of which ramify in the abdominal walls."

In addition to the above cases, I have seen several others which do not differ from the usual type enough to justify their insertion under the title of this paper. In one, the fatal extravasation of fecal matter was the direct result of salines. In another, the onset of the disease was ominous, but rapid recovery followed. The third was saved from a general peritonitis by early drainage. A fourth called the physician on the seventh day for the first time. Nothing could be done for the child, who survived only twelve hours. A fifth was doing very well under medical treatment, when he became collapsed, and died twenty-four hours after an emergency operation by another surgeon. A sixth presented the features of the severest type of intra-abdominal disease not pointing especially to the appendix. Nothing tangible could be made out. Operation was not advised, because no definite indications could be found to guide incision. A day later all unfavorable signs had disappeared. A seventh case is recovering after drainage. In an eighth an appendix was found in violent paroxysmal contractions upon several fecal concretions. The appendix was removed, its stump covered with peritoneum, and the wound in the abdominal wall tightly closed. The results are on the whole encouraging. Surgical interference, however, must be insisted on in the initial stages of this disease rather than when the patient is hopelessly infected.

RECURRING CASES.

The following cases of appendicitis, in which the appendix was removed during the period of abeyance, present one or two conditions hard to explain, and give rise to doubts, first, as to the probable dependence of the symptoms upon the lesion found, and, secondly, as to the advisability of surgical interference.

I. Removal of thickened and adherent appendix in period of abeyance; rapid recovery; subsequent attack like those previous to operation. (Specimen.)

William T. G., aged twenty-four. I saw this young man on January 30, 1893, at Dr. Hildreth's house in Cambridge. I give in detail the history of this attack, in order to make a comparison with that occurring in December following removal of the appendix.

"Monday, January 30th. Yesterday he felt faint in church. In the afternoon he stayed at home on the lounge, and in the evening came to Cambridge. Was pretty sick in his room that night, suffering from pain through his stomach and bowels. This morning he has vomited. He had a pulse of 90, and a temperature of 99.3°. During the night he vomited two or three times, but did not seem to get much relief from it. The abdomen was flat. The pain was exactly in the region of the appendix, where there was a good deal of tenderness, but no tumor. He has had pain in the region of the appendix before, while playing tennis, but never so severe.

"*Physical Examination.* — Temperature 99.2°, pulse 80. Tenderness over the appendix, without dulness. Rectal examination negative. No operation advised.

"February 7th, Dr. Hildreth wrote that soon after my visit a small bunch appeared in the region of the appendix, which gradually subsided. He has been on the whole in very good condition ever since.

"October 18, 1893, Mr. G. said: 'I have had considerable pain since. In June I had an attack which laid me up two weeks. There was not much fever.' October 20th, he said: 'I am very well now, though at times I have a little pain. Since the attack in January I have had in all about five weeks' disability.'"

Operation at the Massachusetts General Hospital, October, 1893. A small incision was made parallel with the fibres of the external oblique muscle, beginning in the right linea semilunaris over the usual seat of the appendix. The cœcum and the parts about the appendix were much congested. The enlarged and thickened appendix was cut off close to the cœcum. The stump was covered in by peritoneum with interrupted silk stitches. A rapid convalescence followed. He was kept on his back four weeks, to allow the scar tissue to get perfectly firm.

On Tuesday, December 18th, I made an examination. He said that on the preceding Thursday morning he had had the same dull pain in the stomach as before, which grew worse and worse. At first he thought he could bear the pain; but it became so severe that he finally went to the doctor, who sent him to bed. The pain lasted till Friday morning, when it left him quite weak. He did not eat anything until Saturday, for he had no appetite. At first the tenderness was general, but afterwards it seemed to be in the same spot as before. It pained him to lie on that side, or to make any motion from one side to the other. The scar was firm, and there was no tendency to hernia. There was no local tenderness.

When the appendix was removed at the hospital, in October, it was very much thickened. Its peritoneal covering was brilliantly injected, and everywhere attached by old adhesions filled with blood-vessels. The mucous surface was dark, rough and reduplicated. The cavity was filled with thin, muddy fluid of dark color. There was no concretion found.

The attack following the operation differed in no respect from those which preceded it. Had the appendix presented normal, or even substantially normal, features, it might be said that there had been an error in diagnosis, and that the attacks were dependent upon other conditions.

Had enough of the organ been left, we might ascribe the late attack to an appendicular colic or a very limited inflammation; but the silk was applied close to the cœcum. The symptoms, therefore, demand some other explanation. The most reasonable one is that the cœcum shared in the appendicular inflammation, and had not recovered its normal condition. On the other hand, the trouble may have been an acute indigestion similar to the previous attack, but of entirely different origin. The pathological condition found exceeds, in the apparent variation from the normal, all lesions I have been able to observe in this class of cases. As far as one can judge, this appendix invited disaster both by the character of its contents, and by its evident condition of chronic inflammation.

The two following cases are reported not only for their intrinsic interest, but because the condition of the appendices found does not seem sufficient to account for the symptoms for which they were removed.

II. Appendicitis; abscess; drainage; recovery;

ten months later an attack like the former, without abscess; removal of appendix which had become almost entirely obliterated; recovery. (Specimen.)

Andrew M. B., aged thirty-eight, shoe-fitter, of Lynn. Drs. Marshall and Lovejoy. Sunday, February 19, 1893.

"I am subject to constipation. When first taken I felt as if some one had hit me in the stomach. After that I had terrible pain. This was a week ago last Tuesday. I vomited several times and have vomited since." There was a rise of temperature for two or three days after the first symptom, the highest being 102°. He had no physician at first and treated himself for colic. He seemed to be doing well. About a year ago he had had a similar attack, which was a very slight one, comparatively. On examination I found a very large tumor in the lower part of the abdomen. The general condition was good. There were no urgent symptoms. Drs. Marshall, Lovejoy, Colman, Little and Harmon were present at the operation. A large incision was made over that part of the tumor presenting in the right iliac fossa. About four ounces of pus of fœcal odor were evacuated through the first incision. The adhesions toward the left were separated with difficulty, and much pus was evacuated from that side. The appendix could be seen in the depths of the wound, large, thick and gangrenous, but so intimately adherent to the surrounding parts that it seemed inadvisable to make any very prolonged efforts for its release. The wound was drained by means of rubber tubes, one deep in the pelvis and another towards the bladder. The whole was packed loosely with sterile gauze.

About two weeks after this there was a discharge of a pint of pus from the wound. The temperature dropped at once to normal. Later it went up to 103°, where it stayed for a week. Nothing could be felt in the abdomen except impacted fœces.

He recovered entirely, and remained well until November, 1893. On November 21st, he came to me and said that "three weeks before he had had a sick spell, coming on like the previous attacks." He had pain in the pit of the stomach; "not a real sharp pain, but a dull sort of pain." With this attack he had a very little fever. In other respects he was well. The pain seemed to go down from the epigastrium to the right iliac fossa, as it did in the attack in February. In answer to the question "How did the last attack begin?" he said: "Well, it is hard to explain. It began with this dull, soft pain in my stomach [indicating the epigastrium.] It kept going down, so that it was a real sharp pain—a stoppage-like pain. Then the trouble would go down to where I was cut. With the last attack there was no vomiting. When I was taken I felt sort of squeamish. It seemed as though I ought to vomit. I have had no other attack since the operation, except that I felt a pain or soreness in my side."

I found a hernia in the scar. There were no other symptoms. I advised first an operation on the hernia, and then, should there be reason for it, an excision of the appendix.

On cutting into the abdomen I found the parts about the cœcum glued together by adhesions, which were easily dissected. The remains of the appendix were found adherent to the outer and lower border of the cœcum. The tip was separated from the base of the appendix by an interval of an inch and a half made up of connective-tissue. I dissected off the tip of the ap-

pendix, and cut the stump close to the cœcum. The abdominal wound was closed immediately by interrupted sutures. A very gratifying convalescence followed. He was sent home at the end of three weeks.

III. Recurring appendicitis; removal of remains of extra-peritoneal and adherent appendix. (Specimen.

Joseph H. M., aged twenty-nine, Washington, D. C., January 1, 1894. This patient has always been in good health up to the time of the present illness. About four years ago he had an attack of indigestion, as the physician in New York thought. There was severe pain through the lower part of the abdomen (indicating a spot a little to the right of the median line, between the umbilicus and the pubes.) This pain lasted about a week, accompanied by slight fever. The pain was intense, followed by vomiting. He recovered from this very well. He was not conscious of a bunch in the side at any time. The next attack was about a year after that, and resembled closely the first. The pain was in the same place, was very acute, and lasted about the same length of time. The next one was six months after the second, and was very similar. About six months ago he was taken, after getting tired, with what was again supposed to be indigestion. This was accompanied by pain in the same place. The muscles over this part of the abdomen were rigid and hard. "I was all drawn up, and it was about a week before I could stand up straight. The whole effect of this attack lasted about three weeks." About the middle of November he had another attack, with which there was some fever. The physician discovered a swelling in the right side at that time. "I have lost about three weeks in the last year. Between the attacks I have a great deal of soreness in the same spot."

I found the patient rather pale and spare. In the right iliac fossa there was a tumor about the size of the finger, hard, somewhat irregular, and only slightly movable. This tumor was situated apparently at the outer border of the cœcum, and behind. Its irregularity and hardness suggested malignant disease. The diagnosis of appendicitis was made, and an operation was advised. This operation was performed on January 8, 1894. The parts about the cœcum were extensively infiltrated by an inflammatory mass, in the centre of which the remains of the appendix were found. This mass lined the right iliac fossa and extended under the caput cœci to the brim of the pelvis. The adhesions could be separated only with the knife. The rounded end of the appendix was adherent to the cœcum, its outer border about at a level with the anterior superior spine of the ileum; the base of the appendix was in its usual position at the brim; between the two there was nothing but cicatricial tissue; the whole intervening portion had been obliterated. I removed the tip and the stump of the appendix close to the cœcum. Its lumen was so large that it seemed best not to close the wound at once. The patient has made, thus far (January 17th), very satisfactory progress, and will undoubtedly recover.

The appendices removed in the two last cases show, as you will see, very similar gross appearances. The chief difference is in the size of the remaining fragments. In both, the central portion has disappeared, and its place has been taken by connective-tissue. In each instance the tip is smooth, rounded, and firm. The peritoneum is injected. Internally the mucous surface is velvety and reduplicated. The closed cavity

of the tip contained a thin fluid. In Case III no cultures could be obtained on agar-agar.

In Case II ten months have elapsed since the first operation. The micro-organisms have been imprisoned in the cavity of the tip long enough to deprive them of their virulence and activity, though this is not a fact resting upon any bacteriological investigations of the case. The wound was closed immediately in Case II because the appendix was opened only at the base, and extravasation was prevented by covering the stump with peritoneum.

In Case III the opening was so large in the appendix, and the chances of contamination so great, that I packed the parts with gauze and left the wound partly open. The harmlessness of the contents, as shown by sterility of the cultures, proves that this precaution was unnecessary. Drainage is all the more to be regretted because of the increased liability to hernia.

Case II is interesting also because of the trivial remains found after one of the most extensive abscesses in my whole experience. Nothing could be found except a slight induration behind the cœcum, and the contiguous cicatricial tissue in which the appendix was found embedded.

In Case III, on the other hand, in which there was either absorption of the abscess or rupture into the bowel, there was an extensive induration which involved the whole right iliac fossa.

Whether these operations, viewed solely in the light of the condition found, were justified or not may be a matter of opinion. The appendices can certainly do no harm now. From all the evidence to be obtained beforehand, the operative interference was well justified. Indeed, if we remove every appendix which is probably or even possibly diseased, we shall save many lives and prevent much suffering, even if we occasionally perform an unnecessary, though safe, operation.

TWO CASES OF CHANCRE OF THE EYELID, WITH AN ACCOUNT OF THE MANNER OF INFECTION.¹

BY MYLES STANDISH, M.D.

Ophthalmic Surgeon, Massachusetts Charitable Eye and Ear Infirmary; Ophthalmic Surgeon, Carney Hospital; Assistant in Ophthalmology, Harvard Medical School.

CASES of chancre of the eyelid are not unknown. There are some thirty cases in medical literature; but there is every probability that the very rarity of the affection has caused other cases to be overlooked in the haste of large ophthalmic clinics, as the infection, in a large proportion of cases, takes place at the margin of the lower canaliculus, and the amount of swelling which accompanies the lesion is very great, so that as a result the gross appearances counterfeit an ordinary lachrymal abscess so exactly as to easily lead to a mistaken diagnosis.

The two cases I am about to report are of interest from the fact that in each the manner of infection of an innocent person was distinctly traced, and are therefore, of importance from a prophylactic point of view.

The first case was brought to the out-patient department of the Carney Hospital by Dr. F. W. Stuart, with the following history:

H. K., a man thirty-one years of age, married, had first noticed a swelling at the inner angle of the lower

¹ Read before the Boston Society for Medical Improvement, January 8, 1894.

lid of the right eye ten days before, attributed by him to a poisoning of the lid from a splash of green paint which he had received in the right eye a day or two before the swelling was discovered. The gross appearance much resembled an active lachrymal abscess. There was a rather large, rounded swelling at the inner angle of the lower lid, red and slightly painful when touched. Upon examination there was discovered in the centre of the tumor a round infiltration, hard and surrounding the opening of the lower canaliculus; no abrasion of the skin or conjunctiva was discovered, but such a condition might have been easily overlooked as the amount of swelling was so great that the lid could not be everted in order to get a good view of the opening into the canaliculus. The patient had always been well and robust, and there was absolutely no venereal history. There was a history of considerable pain locally the past week. There was one small pre-auricular gland to be felt.

The patient was admitted to the hospital; and in the course of four or five days not only the pre-auricular glands swelled rapidly but the sub-maxillary glands on the right side became very rapidly enlarged so that in the course of five days there were three glands below the angle of the jaw as large as hen's eggs.

It is but fair to state that during this period he developed a pharyngitis and tonsillitis with a high temperature, and was so ill that he kept his bed.

As soon as the fever subsided, the patient becoming dissatisfied, left the hospital and returned to his home, and came again under the care of Dr. Stuart. Both in the hospital and immediately upon his return home, active mercurial treatment was maintained. The swollen glands diminished in size without suppuration.

The patient was next seen by me a little over two months later, when he came again for treatment. He then had an active syphilitic iritis in the right eye, the same eye upon the lid of which the initial lesion was situated. The pupil was small and its margin attached to the capsule of the lens throughout almost its entire circumference. Under the active use of atropine and hot fomentations, however, the synechiae were all pulled off, and I again lost sight of the patient; but Dr. Stuart informs me that subsequent to the iritis he had a characteristic secondary eruption appear.

Dr. Stuart was much interested in the case, and undertook an investigation as to the manner in which the original infection was acquired; and by his kind permission I am enabled to report his results.

The patient was, as I have said, a married man and lived with his wife in a small house in South Boston; the only other member of the household was a male boarder. Upon investigation this boarder was found to be suffering at the time of the original infection from a secondary syphilitic eruption. The two men occupied different rooms, and only used one article in common, namely, a roller-towel over the sink in the kitchen. It was their habit upon coming in from their work at noon and night to go to this sink, turn on the water at the faucet and wash their hands and faces in the running water, and then to use the before-mentioned roller-towel to dry their hands and faces. There is no doubt but the disease was transferred from one man to the other by the means of this towel.

The subsequent history of this family is also interesting.

The patient was warned repeatedly, both by Dr. Stuart and myself, as to the danger of infecting his

wife; nevertheless, during the secondary stage he did infect his wife. The initial lesion was upon the vulva. At the time of the infection the wife was four-and-a-half months pregnant, and subsequently, at full term, she gave birth to a syphilitic child, which died a few weeks after birth.

The second case which I have to report came also to the out-patient department of the Carney Hospital about four months before Dr. Stuart brought his case there. He was a man twenty-five years of age, unmarried, and a brakeman upon a freight-train on a railroad leading out of Boston. He reported that about two weeks before—he could not fix the exact date—he had gotten a hot cinder in his eye, since which time it had given him more or less trouble. Upon examination, the lower lid was seen to be considerably swollen and reddened; and when the lid was everted, an ulcer, a centimetre long and about half as broad, was found in the conjunctiva of the lower conjunctival sac. This ulcer had sharp edges, a grayish, dirty-looking base, covered with a somewhat viscid, yellowish discharge. The base of the ulcer could be felt through the lower lid to be a dense, firm induration. The pre-auricular glands were found to be hard and about the size of cherry-stones.

A diagnosis of an initial syphilitic lesion was made, and he was given an ointment of the red iodide to put into the eye; and a pill of hydrarg.-protiodid. (gr. $\frac{1}{4}$, t. i. d.) was prescribed. The appearance of the ulcer was such, however, that I did not feel absolutely sure but what it might be tubercular.

The patient was well and strong, and there was no tubercular or syphilitic history to be obtained. Dr. J. J. Thomas was kind enough to make an examination of the material obtained from the base of the ulcer, for tubercle bacilli. None were found. A week later I removed a portion of the tissue itself from the margin of the ulcer. Dr. Thomas examined this also, and reported that after a very careful search he was satisfied that there were no tubercle bacilli in the specimen.

In the course of a week's time from the first visit, the pre-auricular glands became much enlarged, and soft to the touch. Having satisfied myself that the diagnosis was correct, I questioned the man to see if I could determine the source of the infection. I found that our patient was a brakeman upon a local freight-train, the crew of which consisted of two other men and himself; that they occupied more or less a small car carried on every freight-train for the convenience of the crew, called a "caboose"; that in this they changed their clothes and washed up when they were through their work; but that they did not sleep in the car. Upon inquiry, I ascertained that the other brakeman on the train had had of late some kind of an eruption upon his face, which from the described appearance, duration and an acknowledged history of a recent initial lesion was in all probability an eruption of secondary syphilis. All the men upon the train used the same towel upon "washing up" when their work was over.

The patient was a very unreasonable man, hard to manage; and when my diagnosis was finally told him, took offence and ceased to attend the clinic.

I saw him, however, quite by accident, several months after he ceased to come to the hospital; and there was no doubt in my mind but what he then had an eruption of secondary syphilis.

The method of infection in these two cases is, to my mind, of great interest. It is evident that in roughly drying the face the delicate conjunctival surface at the edge of the lids could be easily abraded, as no matter how carelessly a towel is used, every one is sure to dry about the eyes when the face is dripping wet, to prevent water entering the eyes upon opening them.

It seems to me to follow, as corollary, that, if a chancre of the lid can be acquired in this manner, that a chancre of the lips or edge of the nostril could be acquired in the same manner. The moral is evident: A public towel is an abomination, and should be abolished from all workshops, railroad toilet-rooms, and other public places.

ON SPERMATORRHOEA AND INCIPIENT HYPERTROPHY OF THE PROSTATE, AND A PROPOSED METHOD FOR ITS TREATMENT.

BY RICH. HOGNER, M.D., BOSTON.

A LONG time is always necessary to collect facts; and as it is better, moreover, that they be collected from widely-spread sources, I have not hesitated to communicate the few cases noted below (interesting in themselves, but still more through the great groups of diseases to which they belong), in the hope that more attention may be drawn to prostatitis, especially to that form I have found in spermatorrhœa, and to incipient hypertrophy of the prostate.

During the past summer six or seven youths, between the ages of nineteen to twenty-eight years, came at very nearly the same time under treatment for spermatorrhœa, — *post masturbationem*. All had been previously treated by the "usual methods," but without improvement. The "usual methods" were pursued also by me with physical and psychical improvement in view, besides exercises in the open air, bathing, encouragement, sedatives, cold-water spinal douche, etc.; moreover, *sond à demeure*; but all in vain.

The cases were in many respects alike but also in some points very unlike.

Concerning the usual symptoms it may be mentioned that the frequency of the ejaculations varied between two or three and ten or twelve a week. The conditions of the prostate were the most interesting part in these cases. Its amount varied considerably, from being increased so that the apex could not be approached with the finger, to being rather diminished so that it was palpable everywhere with a very slight movement of the finger; and the consistency was in the former case more or less fleshy (sometimes giving the impression of swelling around a firmer part); in the latter, more hard, without any swelling at all. The former groups (four or five cases) belonged, as to duration and symptoms, to the milder ones; the latter to those of longer continuation and severity, where the ejaculation often occurred without feeling. In all the cases the prostate was found to have an increased sensitiveness or pain to the touch, either over the whole organ or over a portion of the same, in one case apparently only in the region where the lateral lobes begin to diverge, a pain which I have not yet found in uncomplicated cases of masturbation. The symptoms suggested chronic prostatitis in different stages, occupying most frequently the whole organ, and — with regard to the frequent ejaculations — in my opinion, especially the muscular elements. And why would this not be so? The prostate, an organ both muscular for ejaculations

and follicular for secretions, becomes during the spermatorrhœa more strained than under normal conditions. In spite of spermatorrhœa, the "patients" often continue with masturbation; and the prostate muscles, moreover, appear to remain (if I may use the expression) in a kind of "half-primed" state, or one of "constant expectation," and to be in a sickly, irritable condition, with the result that sometimes only the least influence is necessary to produce ejaculation. A hypertrophic gland is in a hyperæmic semi-inflammatory condition; and a muscle which is unnaturally strained often becomes the seat of inflammation. In the spermatorrhœas are found, therefore, the possibility for both a folliculitis and a myositis of the prostate, *per continuitatem* affecting each other. The discharge from prostatic follicles forms a part of the sperma just as certainly as the secretion from the vesiculi seminales; then why should not a follicular prostatitis be primary as well as a spermatocystitis? The prostate gland has surely a double function (secretive and ejaculatory), while, on the contrary, the vesiculi seminales have chiefly only one (secretive); therefore the prostate becomes strained proportionately in double measure during spermatorrhœa, while the vesiculi seminales are so only in one function. Therefore, it seems to me, that the prostate can be primarily diseased as well as the vesicles.

In his treatise Dr. J. Lloyd says²: "In the majority of cases where prostatitis is thought to complicate a urethritis it is the seminal vesicles which are the seat of the inflammation, and not the prostate at all."

When Dr. Lloyd thinks that the urethritis spreads through the ejaculatory ducts, why should it not be carried through the fifteen to twenty excretive follicular ducts which empty below on *pars prostatica urethræ*? I will not speak further on this subject, but maintain that with spermatorrhœa (which is here especially treated of) the prostate gland is just as directly affected as the other genital organs.

The intention is not to draw general conclusions from a few cases; the attempt has been rather to express my impressions and reasons why the prostate began to be treated with massage as in other cases of myositis; while nerve-pressure³ was given at the same time, and in some cases, moreover, gymnastic movements so applied as to lead the blood from the pelvic viscera.

Massage was given once or twice daily per rectum (while the patient was recumbent with elevated pelvis, at the same time placing his fists under the buttocks), partly while the sound (solid No. 10) lay within, partly after it was withdrawn, and continued as long as possible, that is, only a few minutes, as long as the physician can endure it. As a conductor during the massage the sound is of great value, because it makes the prostate more approachable and steady; moreover, it causes the massage to be so much more effective by reason of the double pressure, which is given by the finger per rectum and the instrument per urethram, a

¹ On Spermatocystitis (Inflammation of the seminal vesicles). By Jordan Lloyd, M.D., F.R.C.S. *Lancet*, October 31, 1891, pp. 97, 974, etc.

² *Loc. cit.*, pp. 975, 976.

³ With "nerve-pressure" is meant, a local pressure on a nerve (trunk, branch or plexus), given in such a way that the nerve is pressed for some seconds firmly between the tip of the finger and a more or less deep-lying bone, while at the same time the hand is made to tremble so that under the pressure of the finger the vibration is transferred to the nerve. The movement is intended to create a molecular irritation or change by means of which one seeks to transform the abnormal condition — as far as it can depend on a centropinal change — to a normal one.

pressure which becomes more local than that between the finger and ramus pubis, against which the organ otherwise is resting when the sound is removed.

The cases treated became so much better after two to three weeks that the subjects considered themselves well. The severest was an upholsterer, twenty-eight years old, who had tried "all kinds of remedies" for five or six years, but without success. The patient had a spermatorrhœa appearing each or every second night, and sometimes as many as three times in eight hours. The powers of body and mind were depressed; but the patient was able, however, to continue his work. The prostate was not swollen, but rather small and hard; but what impressed one most was its excessive tenderness, equally spread over the whole organ. Massage and nerve-pressure were employed once daily; also a promenade three-quarters of an hour long before and after each treatment. After two weeks the treatment was discontinued, because one ejaculation a week seemed to the patient to be "nothing." The general health had improved considerably. The tenderness in prostate had disappeared.

In comparison with these cases was one with incipient hypertrophy of the prostate, a man thirty-three years old, who had been married five years, who sought a consultation ostensibly for the reason that for two years past "it had dropped so long" after urination. No stone; no stricture. The urine was clear, passed perhaps more frequently than formerly. The bladder discharged its contents wholly; and still there was a desire soon after to urinate again, so that the patient did not feel comfortable before he had passed some drops more. The prostate gland, of exceedingly fleshy consistency, was considerably enlarged as a whole. The apex of the right lobe was especially difficult of approach by the finger. The lateral lobes felt knurly, especially the right one, in the upper part of which, moreover, a stringy mass of lobes was felt proceeding from the lower inner part to the upper forward part, and gave the impression of enlarged, perhaps somewhat dislocated vesiculi seminales; which mass of lobes as well as the prostate as a whole was noticeably tender to the touch. It took a long time to introduce the catheter; also it had to be inserted deeper than usual, and the posterior part of the urethra was excessively tender, bleeding easily. Gonorrhœa had never existed; neither spermatorrhœa; but the man had, nevertheless, masturbated.

Among formerly employed methods was used — but without success — electrolysis. The treatment now was with massage alone, with and without the sound, on the prostate gland twice daily (except Sundays).

After two months' time the patient's "dropping" disappeared, so that it was "nothing to speak of," and the prostate became diminished so much that it could almost be considered normal, was rather hard and not swelled at all. The knurly character of the left lobe had disappeared, and only a suspicion of unevenness remained in the right lobe. The stringy mass already mentioned had disappeared, and instead somewhat enlarged ordinary vesicles were felt above the right lobe of the prostate. The tenderness had also disappeared.

That especial importance was attached to making the sound, orificium urethræ and the fingers aseptic, scarcely need be mentioned.

Several years ago I had already tried to treat the diseases mentioned, with the use of the sound (then without massage), but no particular success was met.

The signal success resulting from last summer's experience may, therefore, be ascribed alone to the massage.

As stated, the changes of the prostate, in the cases of spermatorrhœa examined, have been regarded as a prostatitis and treated as such; and also the condition in the case of incipient hypertrophy of the prostate referred to, in which the prolonged dropping (a symptom common, moreover, to the senile prostatic hypertrophy), seems to me to indicate that the changes in the prostate even spread to the muscoli detrusor and sphincter vesicæ, both of which connect with the prostate muscles.

Therefore the case can rightly be considered as hypertrophia prostatæ *præ senilis* or incipiens, which was arrested by massage.

But if, instead, the prostatitis had continued, it is probable that the prostate would have become in time harder, and fibrously hypertrophied, that the urinary troubles would have increased, and that the subject would finally have had a regular hypertrophia prostatæ senilis.

The spermatorrhœa with its abnormally exaggerated secretion and ejaculation (probably from the beginning tropho-neurotic and neurotic, but afterwards just as much musculo-glandular in its pathogenesis), it seems to me that a serious circulus vitiosus is established; a nervous irritation has increased the secretion, and this, in turn, the ejaculations, that is, caused the muscular strata to be unnaturally primed or active, which has an influence on the innervation of the prostate, this on the secretion in the follicles and in the remaining genital organs, etc. To this is now added, moreover, the mental depression and the great loss of the specific "vital energy" of the sperma, which in turn also contributes to the diseased condition. Massage was destined in this case to break a link in such a chain.

If prostatitis has been found in spermatorrhœa, then one must imagine the stages preceding, developed by degrees through the masturbation, that is, stages of irritation which finally (through accidental injuries, taking cold, a hurt, etc., or most commonly through continued straining) merge into a regular inflammation. The condition can be the same after exaggerated, natural ejaculations and even so in the irritated condition of the prostate following gonorrhœa. In short, several causes, especially sexual ones, seem to be found, which very early call forth a condition of irritation in the prostate, which from one reason or another is easily transformed into prostatitis muscularis, which, moreover, as in other cases of myitis, etc., untreated, continue through life and increase by degrees; and herein, I consider lie, in great measure, the causes of the frequently occurring "hypertrophia prostatæ senilis," so much the more, as we can easily imagine here a new "circulus vitiosus." When the prostate has grown to a certain degree, it causes a hindrance to the passage of urine. The walls of the bladder become hypertrophied through a process in all respects like a myitis of exceedingly long duration. The affection of the muscles of the enlarged bladder extends also to the prostate muscles (these muscles being so closely connected), and so the hypertrophy of the prostate increases, also the difficulties of urination. That such a long-continued muscular prostatitis is transformed into hypertrophy and not into atrophy certainly depends on the great quantity of blood, physiologically located in the genital region.

W. White says⁴ that one must, from the theories concerning prostate hypertrophies, provisionally accept that of Velpeau (Thompson): "The growth or growths, which make up the enlargement in prostatic hypertrophy are analogous to those fibro-myomata so frequently found in the uterus." It seems to me, rather, they are analogous to metritis hypertrophicans. Either may be the case. But just as the fibro-myomata certainly have been preceded by an irritation, just as the metritis (partialis or universalis) which are treated with massage with the greatest success according to Thure Brandt's method, just so surely have we even seen an incipient hypertrophy or a prostatitis removed by massage. As metritis often depends on something connected with the sexual life (such as, for example, after colds or hurts, especially during, or immediately preceding or following menstruation, after partus, after infectious coitus, etc.), we have here also a similarity between the probable stages of both fibro-myomata or at least of metritis hypertrophicans and the hypertrophia prostatae senilis; the latter of which, for reasons mentioned, seems to stand in relation to the sexual life, an assumption which is further strengthened by the fact, that a bilateral castration diminishes the senile prostatic hypertrophy.

When White asks, "In what cases is a purely expectant treatment proper?" he answers, "Only in those in which enlargement has produced no symptoms, and catheterism is easy and shows no residual urine." I will answer, on the contrary, that every enlargement, every tenderness of the prostate should be treated, in the attempt to prevent hypertrophy, which the surgeon can so beautifully operate upon, but with uncertainty of cure.

It is unfortunately true that one seldom finds a person willing to be treated—at least for any length of time—for a sickness which has not appeared; but I believe, if my comprehension of the beginning of "old men's troubles" is the right one, both that it is the duty of the physician to warn the young or middle-aged man (who, moreover, has already noticed, perhaps, the dropping and prolonged urination) of what can follow if he lives; and that there will be many who would gladly undergo preventive treatment. If we find, even accidentally, during the examination, the prostate *in stadio irritationis* or *in statu mytico*, then the time has come to attempt a treatment.

At present I know no better treatment than massage; but if science finds a less laborious one, so much the better.

It is assumed that hypertrophia prostatae senilis must have its curable stages. May attention be called to this, and testimony from many directions throw light on all sides of this important subject!

A FRENCH CASE OF ILLEGAL PRACTICE.—A curious case of illegal practice is reported from the small town of Sarrao in France. A woman dying in advanced pregnancy, the priest, who was present during her last moments, persuaded a person who was at her deathbed to perform Cæsarean section, in order that he might baptize the child. The authorities, considering this practice to be illegal, proceeded against the operator, who was proved guilty of practising medicine without a qualification, and was fined three dollars.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

NEW REMEDIES IN DERMATOLOGY.

WE quote from a careful *résumé* of this subject by Dr. A. Strauss,¹ some of the more important items.

Europhen-Bayer.—Gottheil, of New York, saw the best results from the use of this drug in ointment form, in tertiary syphilitic ulcerations. Three cases were quickly healed, one was much improved. Brilliant results were also obtained in tinea versicolor, and in tinea circinata. No effect was produced on acne and folliculitis. Pruritus senilis, alopecia areata, and keratosis pilaris were improved, but no more than by other methods. It proved of value in cases of chronic eczema, of none in acute. Six out of seven cases of psoriasis showed as good results as after treatment by chrysarobin. The remedy was chiefly used in the form of a ten-per-cent. ointment, which proved unirritating and innocuous. An Italian observer has noted better results in venereal ulcers from europhen in powder than from iodoform, while he was less successful in syphilitic gummata. The absence of odor is emphasized, in comparison with iodoform.

Amylum Iodatum.—This has been recommended as an application in place of iodine, in the following ointment:

R Amyli iodati	3.0	
Lanolin	30.0	
Ol. Calami	gtts. iii	M.

Resorcinol.—An amorphous, brown powder, smelling of iodine, compounded of resorcin and iodoform. Dr. Bielajew saw good results from this powder in chancres, ulcers of the legs, scabies, psoriasis, eczema, lichen, and in badly healing wounds. It has a very favorable action on pruritus, but must be used in its purity only in gangrenous, or very torpid ulcers.

R Resorcinol	5.0	
Talcum ven.	20.0	M.

Hydrargyrum Resorcino Aceticum.—A dark-yellow, crystalline powder, insoluble in water and mineral oils. It was used by Ulmann in the form of injections for syphilis, and was found to correspond in local reaction with gray oil and thymol-mercury.

R Hydrarg. resorcino-aceticus	5.6	
Paraffin. liquid	5.5	
Lanolin anhyd.	2.0	
(1 ccm. contains 0.387 of the metal.)		

THE TREATMENT OF ACNE.

Jamieson,² in an article on the subject of acne, asserts that in treatment local measures are of the first importance, while constitutional regulations are necessary as an adjuvant. The increased secretion of the sebaceous glands must be combated by forcing out the hardened sebum by a watch-key or comedo extractor, taking care, however, to use no force. Afterward douching, spraying or bathing in very hot water is effective. The soap selected should be a neutral or superfatted one, preferably one in which the alkali is potash rather than soda. A superfatted soap with sulphur, or Eichhoff's resorcin and salicylic soap may be cautiously used. The auto-inoculability of the acne pustules may be combated by touching the beginning

⁴ The Present Position of the Surgery of the Hypertrophied Prostate. By J. William White, M.D., *Annals of Surgery*, August, 1896, p. 166, etc.

¹ Monatsheft. für prakt. Dermatol., Bd. xvi, No. 10.

² British Journal of Dermatology, January, 1894.

papules with a solution of ichthyol in water, one part to four, or when pustules have appeared, by painting each with pure carbolic acid, and afterward coating with flexible collodion. [The latter procedure should be used sparingly and with [great caution. — REP.] When the pustules are large and inflamed they may be covered with Unna's mercury and carbolic acid gutta-percha-plaster-muslin, as has been recommended by Malcolm Morris in the case of boils. Lotions are more efficient than ointments. Sulphur is of great value, both for its action in exfoliating the outer layers of epidermis, and in antagonizing the growth of the pus micro-organisms. Precipitated sulphur with spirits of camphor, glycerine and lime-water may be employed, or when irritative effects are feared, the sulphur may be combined simply with calamine lotion. It is usually best to apply the sulphur lotion at night, washing it off with tepid water in the morning, and then dusting the face with a bland powder, as

	Boli Armenise, q. s.								
	Plat pulvis colorata.								

For the ordinary case of acne rosacea the sulphur and calamine lotion is advisable. The dilated vessels may be destroyed by the scarifier or by electrolysis with a fine needle. When the pustules are very deep, they may be opened with a fine knife; and when large and obstinate, Unna's salicylic and creosote plaster as used in lupus, is effective. The best are those of the proportion of fifteen to thirty, or twenty to forty. The plaster is cut into strips and accurately applied to the whole area affected. It should be kept in place by a muslin bandage or by a cotton mask. The plasters are removed twice a day, the parts washed with superfatted potash soap and warm water, and then fresh plaster applied. This is kept up until the face is too tender for further application, or until the pustules have flattened down. The raw surface is then covered with Unna's zinc-ichthyol-salve-muslin. Afterward the treatment with lotion and dusting powder may be followed with effect.

Another method, which is hardly so satisfactory is the use of a strong resorcin paste, to exfoliate the epidermis.

It is rubbed on lightly twice a day, without the use of water, and occasions some inflammation and pain. When the latter effect has been produced, a simple powder should be substituted until the desquamation has ceased, when the sulphur lotions may be employed.

Internal treatment consists in combating all errors that can be discovered. A wineglassful of Hunyadi Janos water in a tumbler of hot water taken on rising is an effective aperient, and iron, alone or in combination with sulphate of magnesia, is often indicated. Ichthyol is recommended in capsules containing from three to five minims twice a day.

Diet is to be carefully regulated. Water is to be taken freely midway between meals. Hot liquids and spiced dishes are to be avoided in acne rosacea or when there is a tendency to flush; as well as exposure to heat from the sun, or to the snow or sea. A cold sponge-bath in the morning, with the addition of salt to the water, is a stimulant to the cutaneous muscles.

Riding is especially extolled as the best form of out-of-door exercise.

THE INFLUENCE OF SOLAR RAYS ON THE SKIN.

Bowles^{*} considers from his observations on sunburn that the subject is of wider scope than might be supposed, and one that must claim the attention, not only of dermatologists, but of physicians, surgeons, physiologists and physicists. A previous paper by the same writer was published in the *Alpine Journal* in November, 1888.

It is admitted that the sun on snow burns more quickly than on rocks or in valleys, although the heat may be felt more in the latter situations. Veils, masks and snow-glasses are only adopted when the snow is reached. This seems singular, in consideration of the fact that the heat rays must be occupied in melting the snow and thus rendered latent. Glass and iron workers do not become burnt, although subjected to an intense heat; and it is maintained that the radiation from heated rocks and valleys causes a far greater heat than can be present on the snow — and yet one is not sunburnt. Hence there must be some other factor in sunburn than heat alone. Tyndall declared that he was never more burnt on the snows of the Alps than he was while experimenting with the electric light at the North Foreland lighthouse.

Instances are enumerated where several people have been sunburnt on the same day (when the heat was not excessive) who had never been burnt before; and these experiences raise the suggestion that the sun's rays are at times acted upon by atmospheric, electrical or other causes in such a way as to make their effect similar to that produced when the rays are reflected from snow. Sunlight reflected from freshly fallen snow has a greater burning force than that reflected from older snow. The writer has made numerous experiments in the Alps that show that when the face is painted there is no burning, and that on snow where one burns most, the temperature is lower than that on rocks and in heated valleys. The experience of an English officer in India, who had shown great susceptibility to the effects of the sun's rays is related. He had noticed that exposure to heat rays emanating from a source of low chemical activity, was never injurious in its effects, while men working with powerful arc electrical lights, as search-lights, were constantly affected in the same way as from direct solar rays, although the radiant heat from the search-lights was comparatively mild. From this he concluded that sun-stroke and sun-fever were not due so much to the heat of the sun as to the chemical power of the rays; and hence he argued that if he "treated himself as a sensitive plate, and enveloped his body in any color between yellow and ruby-red, he should protect himself to the same degree as the photographer protects his plate." Acting on this theory, he had all his clothes and hats lined with a cheap material of an orange color, with the result that he was able to bear intense heat much better than his comrades; while if the orange material were removed, the old susceptibility returned.

Rays reflected from the snow have an especial influence in producing pigment changes in the skin: This pigment, which is derived from the vessels, may be regarded as an effort on the part of nature to protect the nerves and vessels of the skin from further

^{*} British Journal of Dermatology, August, 1893.

irritation. It is asserted that snails, slugs, lizards and other animals assume darker colors the nearer they are to the snow. The people who winter in Davos become much darker than do those who summer there, although the sun is much stronger than in winter. Another peculiarity is the brown color of the chalets of the higher Alps, while those in less elevated regions, which are not touched by rays reflected from snow, are scarcely, if at all, so affected. The writer has investigated this subject with care, and has found that those parts of the chalets so situated that no rays reflected from the snow could reach them, were of a dirty-white color.

His conclusions are: (1) That heat of itself is not the cause of sunburn; (2) that there is strong evidence for believing that it is caused by the violet or ultra-violet rays of lights reflected from the snow, which reflected light is not necessarily of the same quality as that which is incident; (3) Captain Abney finds that the violet or ultra-violet rays are very strong at high altitudes, and believes that altitude has much to do with sunburn; (4) that altitude alone does not explain sunburn, for one may not be sunburnt on rocks, say at 10,000 feet, and yet be immediately affected on descending to a glacier 3,000 or 4,000 feet lower down; (5) that sunburn and snow-blindness arise from similar causes, and that sunstroke may be associated with them; (6) that rays from the electric light produce much the same effect as sun-rays reflected from snow; (7) that the bronzing of the skin and the browning of the wooden chalets are probably produced by rays reflected from snow.

The "summer eruptions" of Hutchinson [Bazin's *hydroa vacciniforme* — R&F.] — *eczema solare*, etc. — are briefly mentioned at the close as pathological conditions produced by the sun's rays, upon which the bearing of the foregoing observations must be determined by further study.

PATHOLOGICAL ANATOMY OF ERYTHEMA MULTIFORME AND PURPURA.

It has been repeatedly pointed out that erythema multiforme may occur symptomatically in the course of various infectious and inflammatory diseases, especially those of a suppurative character. Among these diseases the most prominent are cholera, typhus, septicaemia, uraemia, endocarditis, diphtheria, gonorrhoea and syphilis. Boeck has noted the appearance of erythema after angina, and abscesses of the tonsils. Finger himself has seen two instances: one of erythema maculatum et figuratum in a severe case of uraemia; the other of erythema annulare of the backs of the hands and forehead, in a case where an extensive ulcerated initial lesion was found in the rectum.

These erythemata may be interpreted in various ways. In the cases of uraemic erythema, we may suppose it a toxic erythema. If in the uraemic cases there is a suppurative process in the kidneys, or if, as in the case of abscess of the tonsils, there are deep-lying, local foci of suppuration, the explanation is twofold. It may be due to the absorption of toxins from the pus into the circulation; and in this case the erythema is a toxic one, belonging in the same class with the erythema ab ingestis, and the drug eruptions. But it may also be surmised that a part of the organisms that were the cause of the pus formation, find their way into the skin, and here exercise a local pathological

action. In this case the erythema would be classed as an infectious erythema, caused by a metastasis of bacterial nature. These erythemata are frequently described, and some writers have inclined to the one view, some to the other. Streptococci have been found by Neumann in the urine, in a case of typhoid complicated with erythema maculatum; and in the abscesses of the skin by Laufer in a case of typhoid accompanied by severe erythema multiforme.

Two cases were examined anatomically by Finger. The first case had been diagnosed as typhus fever, in that, three days before death a thickly-diffused papular erythema had appeared over the body, especially marked upon the backs of the hands and feet. The autopsy showed a disseminated diphtheritic process, beginning on the soft palate and pharynx, and extending down the oesophagus into the stomach. There was pericarditis, double pleurisy and metastatic foci in the kidneys and myocardium. From the latter, pure cultures of the streptococcus pyogenes were obtained.

Histological examination of the papules gave the usual meagre changes seen in an erythema. Bacteriologically, however, large numbers of cocci were found, solely in the vessels. The papillary blood-vessels were so densely packed with them that they gave the impression of injected capillaries. In the reticular layer they were found mostly in clumps, situated along the walls of the larger blood-vessels, and were to be seen also in the vessels about the sweat-glands and in those of the subcutaneous tissue. These cocci were arranged in chains and were constant in their appearance; and as the streptococcus pyogenes was cultivated from the metastases in the kidney and myocardium, it is fair to assume that they were the same species. Finger, therefore, considers that the papules of the erythema papulatum were directly produced by the streptococcus pyogenes, carried to the skin through the circulation. The affection may be described as a metastatic, bacterial dermatitis.

The second case revealed at the autopsy, fatty degeneration of the heart, slight atheroma of the aorta, slight enlargement of the spleen, subacute parenchymatous nephritis of both kidneys, together with numerous spots of purpura on the trunk and the extremities.

Microscopically there were found extravasations of red blood-globules in the papillary and reticular layers of the corium, and a remarkable number of polynuclear leucocytes. The latter were found to be especially numerous in the periphery of the hæmorrhagic foci. Small, round cocci, arranged singly or in pairs, were found scattered through the hæmorrhagic foci, and especially in their periphery. They were also found in numerous blood-vessels. The microscopic examination shows, therefore, that there was not simply a hæmorrhage, but also an inflammation, as proved by the presence of the numerous polynuclear leucocytes. These pus corpuscles point to a local inflammatory irritation, such as extravasated blood cannot cause, but which is doubtless produced by the cocci which are brought to the skin by the blood-vessels, and cause both the hæmorrhages and the inflammatory appearances.

These two cases, therefore, are proved by the microscopic and bacteriological examinations to be neither angio-neurotic nor toxic erythemata, but metastatic bacterial dermatitides. It is not possible to predict the frequency of these forms, yet it is probable that

* Finger: *Archiv. f. Derm. u. Syph.*, 1893, Heft v.

many cases of symptomatic erythema, especially those associated with suppurative processes, as tonsillary abscess, suppurative nephritis, pyelo-nephritis and cystitis, have the same etiology. The same may be said of the erythemata in severe typhoid, endocarditis and puerperal affections. The idiopathic erythemata probably have a different etiology. Pieces of skin from two cases of the latter (which had been in alcohol for a long time) were examined, with negative result. A negative result was also recorded in six cases of purpura, which had appeared in connection with endocarditis, pneumonia and diphtheria.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR meeting, Monday, January 8, 1894, the President, DR. C. F. FOLSOM in the chair.

DR. G. W. GAY showed a case of

LIGATION OF BOTH COMMON CAROTID ARTERIES

in a healthy-looking man twenty-seven years of age. When he was seven years old, a small bunch was noticed upon the left side of his neck just above the collar-bone. It grew very slowly, till three years ago, since which time the size had markedly increased, until at the time of operation, it was as large as a small orange. The tumor had always pulsed; this was controlled by pressure upon the artery below.

On July 31, 1892, the left common carotid artery was tied an inch above the clavicle with two silk ligatures half an inch apart, and the vessel was divided between them. No shock or other disturbance of any sort followed the operation. The patient was sitting up in two weeks, and was discharged well in three weeks.

On June 13, 1893, the right common carotid artery of this man was tied in the same manner, as described above, for a small aneurism situated at the bifurcation into the external and internal carotids opposite the top of the thyroid cartilage. This tumor, an inch in diameter, pulsed like the one upon the left side before operation, and had been in existence ten years.

In exposing the artery, a large vein, probably the internal jugular, was wounded with the director, giving rise to a troublesome hæmorrhage from its location at the bottom of a deep wound. On coming out from under the influence of the anæsthetic, it was found that the patient's voice was very hoarse. A laryngoscopic examination by Dr. Farlow showed paralysis of the right vocal cord, due undoubtedly to entanglement of the recurrent laryngeal nerve in the ligature applied to the vein.

The wound healed by first intention, and the man left the hospital in three weeks. Both tumors were free from pulsation. At the present time, the tumor upon the right side has disappeared entirely. The original tumor upon the left side is nearly gone, but about three months ago, that is, three or four months after the last operation, a small pulsating swelling made its appearance over the upper edge of the tumor upon the left side. Evidently a small collateral branch

has found its way into the original sac, and will require further attention. The man is well with this exception, and is at work in a dental instrument manufactory. The voice is as good as ever it was, except being a little weak, when he attempts to shout. The hoarseness has entirely disappeared. There were no cerebral symptoms following either operation.

DR. MYLES STANDISH read a paper on

TWO CASES OF CHANCERE OF THE EYELID.¹

DR. ABNER POST: I have very little to add to Dr. Standish's interesting account of the two cases. The chancre of the eyelid occurs occasionally in other than ophthalmic clinics. I am pretty sure I have seen two cases. The first was referred to me by Dr. H. W. Williams. The ulceration occurred rather on the external surface of the lower lid, so that its appearance differed somewhat from that described by Dr. Standish, as it would naturally. In Dr. Standish's second case the ulceration was upon the conjunctival surface, where it had that grayish base which is described in all these cases and which resembles more or less closely the surface sometimes seen under the prepuce. In the first case of mine the ulceration was very slight and had that reddish appearance which is common to chancres whose ulcerated surface is exposed to the air. It was surrounded by an indurated areola and resembled the chancre more closely than anything else; and it may be worth while to mention that this woman on whom this supposed chancre occurred was the wife of a railroad brakeman employed somewhere in the vicinity of this city, though her home was either in Vermont or in New Hampshire. The brakeman I never saw. This sore had existed some time, the induration increasing. It had been treated in various ways; and I simply suggest the primary syphilitic source as the most probable solution of its cure. There were no pre-auricular glands to be felt, nor were the glands at the angle of the jaw enlarged at all. It began to diminish very slowly, but very steadily under the influence of mercurials internally, and vanished. She was under my observation for a few weeks; but as soon as the supposed primary sore had disappeared, she disappeared, and whether the diagnosis was ever confirmed in any subsequent history I do not know. She was confined to her bed immediately afterwards by some supposed disease of the chest which was acute. Some time or other I shall know the subsequent history of that case; and if it proves to be syphilitic I shall be very glad to report it.

The other case is the case of a child of five, who was healthy up to the time of her infection. The father and mother had become syphilitic after her birth. They had a syphilitic child in the family, and this little syphilitic child lived with the syphilitic father and mother and baby in close intercourse. Her syphilis was evident from glandular enlargement and syphilitic papules which were particularly prominent about the region of the vulva and about the mouth and nose. The mother gave the history of the appearance of a sore on the eyelid which she supposed was an ordinary sty. That was the first thing. The eruption appeared a few weeks after. When I last saw her the other eruption had disappeared. There still remained on the spot of the supposed sty a certain amount of thickening, such a condition as one finds after primary lesions on other parts of the body. The pre-auricular gland

¹ See page 237 of the Journal.

as not enlarged, though the glands about the neck were. I can only say that in her case I believe that the sore on the eyelid was the primary sore, the point at which syphilis entered the system.

I am particularly glad to have such cases reported, because it serves to emphasize the fact that syphilis is not simply a disease of venereal origin, but that it is a disease which is communicated from one individual to another, no matter what the contact or whether the contact be immediate or mediate. The primary sores that occur about the face are very numerous indeed; I have within a month seen four primary sores of the lip. Towels are by no means the only media by which such inoculation takes place. During the same time I have also seen four physicians who have been inoculated upon the hand in some shape or other. It is, I think, hardly extending the subject too widely to draw attention to the other numerous cases which exist about us in which syphilis has been contracted in some other than the orthodox manner.

DR. E. WIGGLESWORTH: I agree entirely in regard to the necessity for such papers as this, and I am sorry that I cannot from memory report any cases occurring in my own individual practice. The public at large are hardly anatomical enough to recognize the distinctions of specialties, and these cases go to the ophthalmologist instead of the dermatologist, as a rule. There is one thing to be said; namely, that these lesions do not always occur at the entrance of the lachrymal duct. They may be found even inside of the lids, as well as outside, or upon the border of the lids. They may be found upon the caruncle itself; and these are, perhaps, the worst cases of all. I recall with reference to the number of reported cases, which Dr. Standish tells us is now about thirty, that when I was in Vienna, in 1866, the cases amounted to only ten. Since then I have not taken the opportunity to look up the number. At that time there were only ten, including those on all parts of the lids, both external and internal. There are now in the Warren Museum three of the preparations of Baretta, which represent very well the appearance of this lesion before, during and after treatment. The sclerosis was upon the upper eyelid of a seamstress.

Our first duty, of course, is to decide whether the lesion is in its nature specific; but even then there is some danger of error as to stage, since papules, or other manifestations of secondary lesions, may occur here as well as elsewhere; and it is not relatively rare to find even gummata in this situation, which belong, of course, to the later stages. The method of infection is by means of the fingers, as the rule. This seamstress had, I think, been sewing some bands to be applied to a person, and perhaps applied them herself, and then carried the finger to the eye. Another case is reported of a man engaged in the "orthodox" practices alluded to by Dr. Post, who felt an itching in his eye, and carried the hand to the eye and rubbed it violently for quite a while. This was followed by a primary lesion. There are other cases where, at accouchements, physicians have infected themselves. But the fact of primary lesions occurring upon the face and other parts, to which Dr. Post alluded, was very well shown this morning in my clinic at the City Hospital. The wife of a laboring man appeared with two primary lesions, which fact is, of itself, relatively rare, just below the angle of the mouth, on the left-hand side; these were of two months' or more dura-

tion. She gave a very good history of initial manifestations; that is to say, red spots, and subsequently papules with dry crusts on top; and, what is especially interesting, stated that they passed by degrees from that condition into the secondary stage of mucous papules; and they are now in the condition of mucous papules, and very well marked. The rest of the body is covered with papules. The general treatment is, of course, the same as when the initial lesion is situated elsewhere.

DR. F. B. GREENOUGH: I have never seen a chancre on the eyelid. Of course, there is no reason why it should not occur there, the only factor being to have the syphilitic virus in contact with the mucous membrane or skin where it may be absorbed, and we see the primary lesion appear in all sorts of places. Dr. Standish does not mention any examination to prove that there was no primary lesion anywhere else. I have no question of the diagnosis or of the primary lesion; but at the same time, in all such interesting cases as this, I think the possibility of primary lesion on the penis or somewhere else ought to be excluded. In the first case he reports I am rather astonished at the size of the glands—as large as a hen's egg. I have seen several chancres about the lips, and one or two on the face, but never saw the glands anywhere near as large as that. I think we owe a great deal to Dr. Standish for his interesting paper.

DR. POST: May I refer to one remark of Dr. Wigglesworth in regard to the rarity of a double inoculation, or two primary sores at the same time? My own experience differs somewhat from Dr. Wigglesworth's, apparently. It is customary to say that the primary sore of syphilis is single, while non-syphilitic venereal sores are multiple. There is certainly some foundation for this, but I should prefer to say that in the majority of cases the primary sore is single; but it may be multiple, exactly as a man may be vaccinated in one spot or in several. It seems to me that the stress that is laid upon a single sore as a diagnostic point of the initial lesion of syphilis is carried too far, and leads to error.

DR. GREENOUGH: I should like to endorse Dr. Post's remarks. Dr. Chenery, who was my assistant at the Dispensary, made statistics. I have forgotten the number, but there are certainly quite a number of cases in which there were two primary sores. I think I have seen three.

DR. WIGGLESWORTH: I merely spoke of the relative frequency. Of course, what Dr. Post alludes to is perfectly true. The case was of especial interest, not only from the comparative rarity of multiple lesions, but also from the fact that we had here two (primary) lesions occurring at the same time, and of the same size, close together, upon an unusual situation, and passing by degrees into (secondary) mucous papules. There was a sore on the mouth of the husband, so that there was an explanation of the source of inoculation.

DR. STANDISH: Concerning the question of the possibility of these patients having an initial lesion somewhere else, in the first case we had a physical examination, and there was no lesion anywhere else; in the second case the man was very intractable, and no such examination was possible. The glands in the neck were very large in the second case—so much so as to obliterate the concavity under the angle of the jaw, so that the line of the face ran straight down to

the shoulder. We must remember he was suffering from pharyngitis and tonsillitis, which may have aggravated matters very much. The situation of these initial lesions, of course, may be anywhere on the outside or inside of the lid.

DR. M. H. RICHARDSON showed

SPECIMENS OF VERMIFORM APPENDICES PRESENTING UNUSUAL FEATURES.²

Recent Literature.

Atlas of Clinical Medicine. By BYRON BRAMWELL, M.D., F.R.C.P., F.R.S. Edin., Assistant Physician to the Edinburgh Royal Infirmary, etc. Vol. II, Parts II and III. Edinburgh: Printed by T. and A. Constable. 1893.

The second volume of this very handsome "Atlas of Clinical Medicine" is now completed with the issue of the third part. We have already noticed the previous issues. In the second and third parts of the second volume, the standard promised at the inception of the work is maintained, and the original excellence of letter-press and plates continues to be realized.

The text of Part II is largely devoted to syphilis and Asiatic cholera, and most of the plates are illustrative of the former disease. The active treatment of the primary sore, and the exhibition of internal remedies before the appearance of secondary manifestations, as advocated in the text, has the authority of Hutchinson, but is not generally regarded in this country as having the sanction of our best authorities.

Part III is devoted to exophthalmic goitre, acromegaly, exfoliative epidemic dermatitis, unilateral hypertrophy of the face. The plates illustrative of acromegaly, taken from a so-called "giantess," are very characteristic.

Clinical Lectures on Abdominal Hernia; chiefly in Relation to Treatment, including the Radical Cure.

By WILLIAM H. BENNETT, F.R.C.S., Surgeon to St. George's Hospital, Member of the Board of Examiners for the Fellowship, Royal College of Surgeons of England, and Lecturer on Clinical Surgery in St. George's Hospital Medical School. With twelve diagrams. London and New York: Longmans, Green & Co. 1893.

These lectures were delivered at St. George's Hospital, and include the cases occurring in the author's wards. The work has the merit of being what it represents, clinical lectures on hernia. It is a valuable one, in that it records the ideas of the writer, a man of ripe experience, who has paid considerable attention to this subject. It is a book that can be read with interest by all, and may be of value to practitioners who meet obscure hernia, which are often very perplexing. A good portion of the lectures is devoted to the symptoms of strangulated hernia. Formerly the symptomatology of hernia was of greater importance than now. The pre-antiseptic fear of opening the sac of a hernia is gone, we hope never to return. To-day the conservative surgeon explores any tumor occupying the seat of a hernia if there are present any symptoms suggesting the possibility of strangulation. The danger of this exploration under modern methods is far less than the inevitable errors in judgment of attempting to mentally eliminate strangulated hernia.

CHRONIC ARSENICAL POISONING FROM WALL-PAPERS AND FABRICS.

THE question as to the form in which arsenic enters the system in cases of chronic poisoning from arsenical wall-papers has been the subject of much controversy. The theory that the symptoms are due in some cases to the irritant action of detached particles of arsenical pigment has received important confirmation in the frequent detection of arsenic in the dust collected from rooms containing arsenical papers. On the other hand, the occurrence of numerous cases of poisoning under conditions most unfavorable to the separation of arsenical dust has led to the theory that, under certain conditions, some gaseous or volatile arsenical compound may be set free from arsenical papers.

Many experiments have been made for the purpose of testing the latter theory, but the results have been, for the most part, adverse, until the recent investigations of Gosio,¹ who found that a volatile arsenical compound could be formed by the action of moulds on organic matter containing arsenic. Hamberg and Bischoff alone of the earlier investigators obtained a volatile compound, which they believed to be arseniuretted hydrogen. The results of Gosio's recent investigations suggest, however, that these earlier views as to the nature of the volatile compound formed were probably erroneous; though it seems quite certain that a volatile arsenical compound of some kind was obtained in the experiments of the two authors mentioned.

Two recent papers by Prof. Charles R. Sanger,² of Washington University, St. Louis, who has repeated the work of Gosio and proved its correctness, form, from a chemical point of view, the most important contribution to the literature of this subject which has yet appeared in this country.

In his first paper the author gives a lengthy but interesting review of the investigations relative to the

¹ The Journal, cxxvi, 201; cxxvii, 185; cxxviii, 340.

² Proceedings of the American Academy of Arts and Sciences, vol. xxix.

subject which have been made up to the present time, including those of Gosio, and describes very minutely the various experiments which he has himself made, including some earlier ones hitherto unpublished, the results of which were, owing to unsuitable conditions, adverse to the theory of the formation of a volatile compound.

A description of these experiments cannot be given, for obvious reasons, in the editorial column. The fact, however, that Gosio's results have been substantiated by so careful an investigator as Sanger, justifies the following brief *résumé* taken from Sanger's papers:

It appears that a volatile compound is generated by the action of the following moulds on arsenical organic matter: *Penicillium brevicaulis*, *Mucor mucedo*, *Aspergillum virens*, and *Aspergillum glaucum*, a few others having been found which have a slight action. Of these the most intense action is caused by the first, a mould discovered on decaying paper, though *Mucor mucedo*, which is more widespread than the first, is only a little less active. The conditions for development of the compound by these moulds are moisture, a temperature from 15 to 35° C. (60 to 95° F.), and a supply of oxygen, without which no action takes place. A large amount of arsenic retards the growth, which goes on best in a ground containing 0.01 to 0.05 per cent. The best nutritive material is a carbohydrate. The development may take place in presence of arsenious oxide or its derivatives, or of arseniates, though the latter seem to Sanger to have given the best results. Little or no action is obtained from the sulphides.

The nature of the volatile compound is as yet unknown. It is not arseniuretted hydrogen, and indeed it is questionable if any arseniuretted hydrogen is formed. Sanger is inclined to the opinion that it is an organic derivative of arsenic pentoxide. It has, however, little resemblance to any of these derivatives thus far isolated.

The author attributes the adverse results obtained in his earlier experiments, and the similar results obtained by some of the other investigators to the fact that there was either too much arsenic for the specific bacteria to tolerate, or else the latter were not present. A partial explanation is possibly found in the fact that many of the earlier investigations were made upon the assumption that the volatile compound formed, if any, must be arseniuretted hydrogen.

The formation of a volatile compound from decaying arsenical matter may now be regarded as settled beyond any reasonable doubt by the investigations of Hamberg, Gosio and Sanger. In this formation we have a complete explanation of those cases of chronic arsenical poisoning which occur under conditions in which the separation of arsenical dust cannot be admitted. Gosio, while admitting that poisoning from arsenical papers may at times be due to the inhalation of solid particles mechanically detached from the paper, believes that in a majority of cases the arsenic is absorbed in the form of the volatile compound.

Sanger's second paper is made up largely of the

record of published cases of chronic arsenical poisoning in which analytical work is included, and of cases which have come to his own notice, in which analyses of wall-paper and urine were made. The chief value of this paper is found in the fact that the analyses, both of paper and urine, in the author's own cases were quantitative. He finds that the amount of arsenic eliminated by the kidneys is very small, varying from 0.002 mgr. to 0.068 mgm. per litre. These results are in accord with those obtained by others who have had experience in this class of cases.

The author concludes that the elimination of arsenic by the kidneys in cases of wall-paper poisoning is very slow. He apparently bases his conclusions upon the fact that, in the cases reported by him, the time during which arsenic still appeared in the urine was usually very long. In five cases, for example, arsenic was still detected after the lapse of 60, 96, 100, 127 and 140 days respectively. The author's conclusions on this point are justifiable only in case freedom from exposure to other sources of arsenic during the periods named was secured. There is, however, no evidence whatever of any such freedom in the history of the cases reported by him. The existence of other sources can hardly be denied. There are apparently some which are as yet undetected. For this reason the settlement of the question of rate of elimination is, we believe, attended with peculiar difficulties, and much work must yet be done before the time required for complete elimination can be determined with any degree of accuracy. Sanger thinks that the question of the limit which can be set to the dangerous amount of arsenic in a wall-paper is one which should be considered very carefully, since Gosio's work and his own has shown that a very small amount of arsenic may be quite as good a source of the volatile compound as a very large amount. He does not think, with the chances for the formation of the volatile compound, that 0.1 gr. per square yard can be pronounced with certainty harmless; and suggests that a quantitative analysis of each arsenical paper be made, in order that the physician may himself decide as to whether the paper should be rejected or not.

A NEW BILL FOR THE ESTABLISHMENT OF A NATIONAL BUREAU OF HEALTH.

THE new bill, prepared by a Committee of the New York Academy of Medicine, for the establishment of a National Bureau of Health in the Department of the Interior, promises, if it meet with favorable consideration in Congress, to give to the country the most satisfactory national health organization that has yet been proposed.

The Bureau, in accordance with the provision of the bill, would consist of a Commissioner, appointed by the President, and an Advisory Council made up of delegates, one from each State, designated for this service by the respective governors.

If, as might reasonably be expected, the members

of the Council are selected from the State Boards of Health, there would then be brought to the support of the national organization the influence of a body of men each of whom has a well-recognized position in his own community, and a legitimate influence upon the representatives of his State in Congress. Their presence on a national board would go far to remove the vague fears that have prevailed in some quarters as to the tendency of a purely central organization to usurp powers, which could more safely and wisely be left to local authorities.

The duties of the Bureau would be to collect and diffuse information upon matters affecting the public health, including statistics of sickness and mortality in the several States; the investigation of experimental and other methods and means of prevention of the causes of diseases; the collection of information with regard to the prevalence of contagious and epidemic diseases, both in this and other countries; the publication of the information thus obtained in a weekly bulletin; to prepare rules and regulations for securing the best sanitary condition of vessels from foreign ports, and for the prevention of the introduction of infectious diseases into the United States, and their spread from one State into another, which rules, when approved by the President of the United States, shall have the force of law; and to ascertain, by a suitable system of inspection, that these rules are properly carried out and enforced; to advise and inform the several departments of the government, and executives and health authorities of the several States on such questions as may be submitted by them to it, or whenever, in the opinion of the Bureau, such advice and information may tend to the preservation and improvement of the public health; and in general to be the agent of the general government in taking such action as will most effectually protect and promote the health of the people of the United States.

The act provides that this Bureau shall be responsible for the making of those rules and regulations which are the foundation of systems of quarantine between the various States of the Union as well as between Nations; yet these rules, having first received the approval of the President, are to be executed, as hitherto, under the supervision and authority of the Treasury Department. While this limitation of the Treasury Department to purely executive functions may be distasteful to the Marine-Hospital Service, it can hardly be claimed, on the other hand, that this body could adequately perform the multifarious duties above set forth.

One function is bestowed upon the Bureau, which is peculiar to this bill, and would probably be of great benefit — the duty of the Bureau to inspect and report upon the conduct of the quarantine establishments formed under the provisions of this act.

State and municipal authorities are permitted to enforce, if they so elect, such measures as are directed by the President, in accordance with the recommendations of the Bureau; but if such authorities fail or

refuse so to do, then the President shall enforce the rules by such means as may seem appropriate to him.

The quarantine sections of the bill have, evidently, been very carefully framed and follow closely the provisions of Senator Harris's bill. No member of the Senate has been more interested in public health legislation than the member from Tennessee, nor is there any one whose opinion would have more weight in that body.

The Bureau is especially directed to take such action, by correspondence or conference, as will tend most effectually to secure the co-operation of State and local boards of health in establishing and maintaining accurate systems of notification of the existence and progress of contagious and infectious diseases; and to extend, if possible, such systems to foreign countries.

In general, the motive that appears to have prevailed in the making of this bill is the one which has led to the most useful public health bodies which the country has so far had. That is to say, the intention seemed to have been to create a central health authority, the business of which shall be the collection of all sanitary knowledge and the prompt diffusion of the same.

If this Bureau is able to deserve the confidence of the country, experience with similar bodies tell us that executive functions will from time to time be given to it. The almost hopeless confusion in which the present Congress is involved, may, possibly, prevent this new measure from receiving the consideration it fairly deserves; but the bill has been so carefully prepared and so wisely framed that we hope it may be insistently presented at Washington until favorable action is taken.

MEDICAL NOTES.

YELLOW FEVER AT RIO JANEIRO. — Yellow fever is reported to be rapidly increasing in Rio Janeiro, the deaths being more than twenty each day.

A NEW ORIFICIAL JOURNAL. — A new medical journal has been published in Paris, devoted to orificial medicine. It is edited by M. D. Magitot and is to be known as the *Revue Mensuelle de Stomatologie*.

HONORS FOR PROFESSOR HENOCH. — The Emperor of Germany has conferred the Order of the Red Eagle, of the Second Class, with the crown and oak leaves, on Professor Henoch who has retired from the chair of children's diseases in the University of Berlin.

A PHYSICIAN'S HOUSE INJURED BY DYNAMITE. — The house of Dr. J. E. Baker in Lancaster, Pa., was seriously damaged last week by a dynamite cartridge which some mischievously inclined person exploded under the porch. It is not often that physicians are thus molested, as even the wantonly malicious seem to have a little respect for a doctor.

THE NEW YORK VEGETARIAN SOCIETY DINNER. — The New York Vegetarian Society held its second annual dinner last week, and had a most elaborate menu. Among the courses were *cream of celery soup*;

Brussels sprouts, cream sauce; Nesselroude pudding; Stilton, Roquefort, and Camembert cheese. It is to be presumed that these were all made either with coconut milk or the juice of the milk-weed.

DEATH OF A HOSPITAL HOUSE-OFFICER.—Mr. Lewis Burrow, a senior house student at St. Thomas's Hospital, London, died recently from septicæmia, resulting from the inoculation of a scratch on one finger while making an autopsy.

THE TOLEDO MEDICAL COLLEGE.—In accordance with the recommendation of the Committee on the Administration of the Medical Practice Act, the Secretary of the State Board of Health of Illinois has been directed to recognize the diploma of the Toledo Medical College as entitling the holder to a State certificate for practice.

THE EIGHTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.—The Eighth International Congress of Hygiene and Demography is to be held at Budapest, Hungary, in the first week of September next. The following is a list of the subjects for discussion in the Hygiene Division:

(1) *Ætiology of Infectious Diseases*; (2) *The Prophylaxis of Epidemics*; (3) *The Hygiene of the Tropics*; (4) *The Hygiene of Trades and Agriculture*; (5) *The Hygiene of Children*; (6) *The Hygiene of Schools*; (7) *Articles of Food*; (8) *The Hygiene of Towns*; (9) *The Hygiene of Public Buildings*; (10) *The Hygiene of Dwellings*; (11) *Hygiene of Communication (Railways and Navigation)*; (12) *Military Hygiene*; (13) *Red Cross*; (14) *Saving of Life*; (15) *State Hygiene*; (16) *The Hygiene of Sport (Inurement and Care of the Body)*; (17) *The Hygiene of Baths*; (18) *Veterinary Hygiene*; (19) *Pharmacology*.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—During the week ending at noon, March 7, 1894, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 53; scarlet fever 28; measles 7; typhoid fever 6; small-pox 6, and 2 deaths. On the 3d of March the steamer *Venetian* of the Leyland line arrived at quarantine with four cases of varioloid on board, one of which was fatal soon after being removed to quarantine. There were no cases in Massachusetts outside of Boston.

DEATH AT ONE HUNDRED AND THREE YEARS.—Ann Cauley, the oldest woman in York County, Me., died in South Berwick March 2d, aged one hundred and three years and seven months. She was born in Ireland.

THE NEW MEDICAL PRACTICE LAW IN CONNECTICUT.—The first semi-annual examination under the provisions of the new medical practice law was held last week in New Haven. Eight candidates were examined by the committee appointed by the State Board of Health, and only five were given certificates.

CONNECTICUT FERTILITY.—A young married couple in Roxbury, Conn., have recently been reported to have had their family increased by the birth of triplets. The father is sixteen years old, the mother is thirteen; and the three new children, a boy and two girls, are said to have weighed twenty-three pounds!

NEW YORK.

THE BOARD OF HEALTH AND FAMILY PHYSICIANS.—At the monthly meeting of the Medical Society of the County of New York, Dr. Carl Beck read a paper on "Pyothorax and its Treatment"; and Dr. W. M. Seward one on "Ectopic Gestation." Dr. Daniel Lewis called up the following resolution, which had been laid on the table at a former meeting: "*Resolved*, That it is the sense of this Society that if the Board of Health is to preserve its influence in the community in the highest degree, it should extend to the family physician the same consideration which one member of the profession owes to another." In advocating its passage Dr. Lewis said that, although the wording of the resolution was somewhat ambiguous, the members present knew very well what it referred to. Health inspectors frequently visited patients of practising physicians and took occasion at these times to prescribe remedies and counsel treatment at variance with that of the attending physician. This was unprofessional, and should not be tolerated. The attending physician should, at least, be consulted before any change in the treatment of a case was made. In the discussion which followed, Dr. Joseph D. Bryant took exceptions to Dr. Lewis's remarks, and denied that the course of the inspector was, as a rule, such as to warrant the strictures made by him. He thought, however, that individual cases and epidemics sometimes occurred where prompt action was called for, and the exigency of the circumstances compelled the inspectors to violate the letter of the resolution while they followed the spirit of it. He therefore proposed the following addition as an amendment: "Provided that such course shall not conflict with public policy." This was accepted by Dr. Lewis, and the resolution was passed as thus amended.

SMALL-POX.—The concealment of cases of small-pox in tenement-houses continues to give the Board of Health serious trouble, and on one day recently no less than ten such cases were discovered. Two or three cases of the disease have occurred at the State prison at Sing Sing, and it is thought that it was brought there by some of the newly-arrived convicts, or else through the rags taken there for sorting by the prisoners. During the week ending March 3d there were reported 80 cases of small-pox in the city, and six deaths; against 29 cases and five deaths the week previous. The total mortality for the week was 857, against 830 in the week ending February 24th.

A FATAL CASE OF SINGULTUS.—A case of death from hiccup is reported from Newark, N. J. The patient was John Carberry, a bar-tender, thirty-three years of age, and the affection lasted more than thirteen

weeks. At the time the hiccupping commenced, on November 29th, he was seated in a barber's chair getting shaved. After a large number of remedies had been tried in vain, a novel operation was undertaken in the hope of saving the patient's life. Under the hypothesis that the source of trouble was irritability of the inferior dental branch of the inferior maxillary nerve, which was communicated to the phrenic nerve, the inferior dental was cut down upon and severed; but this procedure also proved fruitless, although some temporary improvement in his condition followed. The only thing that seemed to be of any service in checking the attacks was ice-cream, which he took freely. He gradually became weaker, and finally died of exhaustion. At the time the hiccup commenced Carberry was strong and robust, and weighed one hundred and fifty pounds, but just before his death he weighed only eighty pounds. No autopsy has as yet been reported in the case.

MORTALITY.—The State Board of Health reports 10,948 deaths in the month of January, representing an annual death-rate of 19.70 per thousand of the estimated population. In December, the annual death-rate was 19.20 per thousand. Influenza became epidemic in December, and 1,000 deaths were attributed to it in December and 1,200 in January. This is more than twice the mortality from the disease during the same months in the epidemic of last year. In New York city, however, influenza has thus far been much less fatal than last winter.

Miscellany.

PROFESSOR TYNDALL AND BOSTON RESOURCES.

In an account of Professor Tyndall's visit to this country in 1872, Miss Youmans¹ publishes some letters of the physicist, which give an interesting revelation of the mental state of even a most highly educated Englishman concerning the commercial resources of Boston. Writing for advice as to his arrangements he says:

August 21, 1872.

MY DEAR YOUMANS: I am in the midst of my preparations here, and shall have them ready so as to enable me to start in the *Russia* on the 28th of September.

I shall need your friendly aid in getting my apparatus through the custom house. . . .

With regard to the lecture rooms, in all of them I must be able to lower the lights promptly. Most of my experiments will be projected on a screen.

I purpose mixing experiment and philosophy in due proportions.

Do your audiences look down upon the lecturer?

I suppose I can borrow an air-pump in New York if I need it.

I suppose if they do not possess ice in Boston, I can have a clear block sent there from New York.

Acids, of course, are to be had everywhere.

Are they in the habit of using compressed hydrogen and oxygen in iron bottles in America; and, if so, could I borrow such bottles?

¹ Popular Science Monthly, February, 1894.

I am taking one screen with me, but I shall sometimes require two. Is such a thing to be borrowed?

Now, like a good fellow, answer these questions within twenty-four hours, and oblige

Yours, ever faithfully,

JOHN TYNDALL.

And again:

FOLKESTONE, September 19, 1872.

MY DEAR YOUMANS: . . . I hope they have clear ice in Boston, also nitric and sulphuric acid; if not, I must stock myself from New York. I have written a line to Dr. Draper on this point; but I should be truly thankful to you if you would make this point out for me, and if the acid is not to be had at Boston, send there a carboy of nitric and one of sulphuric acid.

I am quite shocked at the mass of apparatus I have collected round me. Still I thought it best to take light apparatus—batteries, electric lamps and costly optical apparatus—with me, having just given the experiments with them here.

Yours ever,

JOHN TYNDALL.

MR. LAWSON TAIT'S USE OF ANÆSTHETICS.

In a letter to the *Buffalo Medical Journal*,¹ Mr. Lawson Tait, in replying to Dr. Robinson's remark that few English surgeons "engaged in abdominal surgery give much attention to the kidney in their work,"² says that it is the very care he has given to the study of the effect of anæsthetics on the renal functions which makes him prefer chloroform to ether for abdominal and ovarian surgery. He says that the most important sentences he has ever published in his life are the following:

"The question of the best anæsthetic for use in abdominal surgery is one to which, of course, I have given a very large amount of attention; and it is very singular that in the class of drugs, the action of which there can be the least doubt about, we are, as yet, certainly very unsettled in our views. Like all pupils of Simpson, I began my professional life with a most profound belief in the advantages of chloroform over all other anæsthetics. I have never seen an accident from chloroform, but, partly by reason of the fear of inquests and partly by the example and teaching of Dr. Keith, a belief grew in my mind that ether was preferable to chloroform, and at first I had the impression that the sickness after ether was less marked than after the use of its rivals. I was not, however, very long in discovering that ether has special risks for people with a tendency to bronchitis; and later on I discovered, and have already published the fact, that during the administration of ether the secretion of urine is completely arrested. It was subsequently very forcibly impressed on me that, for patients with damaged kidneys, ether is a dangerous anæsthetic, and although I cannot say that I have seen any fatal results arising from this peculiarity of its action, I certainly have had abundant cause to fear it. My first alteration, therefore, in my views concerning ether, was to limit its application to patients under forty, but even after this I found my confidence in its safety greatly diminished by the fatal occurrence of bronchitis in a case of hysterectomy in a woman aged thirty. In this case the patient's breathing was embarrassed from the moment she recovered from the anæsthetic, her urine was scanty and became ultimately albuminous, and she died on the fourth day from suffocative catarrh, the post-mortem showing that, so far as the operation was concerned, everything was perfectly satisfactory."

The chief reason why these remarks made little impression when first printed in 1884 was the fact that England is emphatically the land of coroner's inquests,

¹ February, 1894.

² What kills after Laparotomy, *Buffalo Medical Journal*, December, 1893.

which are things an English practitioner hates above everything else.

"Coroners seem always fond of making public inquiry to cases of death under an anæsthetic. Every such death therefore, blazoned abroad until the use of chloroform has become a *bête noire* of surgical practice alike for practitioner and patient. Chloroform, when it kills, which it does very rarely, kills on the instant, and, in England, there is an inquest. When ether kills, which it does far more frequently, it kills some days after its administration, and there is no inquest, not even an inquiry.

"To get over the difficulty, I began to use a mixture and soon found that it was a great advance over either of the two anæsthetics used separately. I vary the proportions according to age, increasing the proportion of chloroform from one-third to two-thirds rapidly after forty, and in a case there is any suspicion of renal or pulmonary incompetency.

"Twelve years' experience has driven entirely out of my practice all those disasters which ether brought into it. In a number of administrations, now amounting to a great many thousands, not a mistake has occurred, and alarms occur only where some new and inexperienced administrator will indulge in such fantastic tricks as pushing back the tongue by pressing up the jaw, or violating in some other foolish way the simple rules for administration laid down over forty years ago by Simpson, not one of whose methods has yet been surpassed."

WILLIAM JOHN GORDON FOGG, M.D.

SOUTH BOSTON, March 2, 1894.

At a meeting of the physicians of South Boston the following preamble and resolutions were adopted:

Whereas, Death has removed from our midst our much-esteemed friend and colleague, Dr. W. J. G. Fogg, and whereas, it is fitting that we express our feeling of sorrow at this great loss, therefore,

Resolved, That we gladly testify to our appreciation of his great professional skill, his readiness to advise when called upon by any of us, his honesty of principle toward his medical brethren and toward his patients; all of which we shall ever hold in grateful remembrance.

Resolved, That the death of Dr. Fogg is a loss to the community in which he lived and for which he worked so many years.

Resolved, That a copy of these resolutions be sent to his afflicted family; a copy be published in the local papers, and in the *Boston Medical and Surgical Journal*.

PER COMMITTEE.

NORFOLK SO. DISTRICT MEDICAL SOCIETY. SAMUEL MAGNUS DONOVAN, M.D.

March 1, 1894.

Whereas, it has pleased Almighty God to remove from us our beloved friend and co-worker, Samuel Magnus Donovan, M.D.,

Resolved, That we, the Fellows of the Norfolk South District Medical Society, mourn the loss of a genial friend and an active member of this organization. Cut off in the prime of manhood and in the noon-tide of a useful and honorable career, we have lost a valued member of this Society; the community in which he lived, a trusted counsellor and a skilful physician.

Resolved, That we offer our kindly sympathy to the family of our deceased brother in this hour of mourning.

Resolved, That these resolutions be entered upon the records of the Society, a copy of the same be forwarded to the family of the deceased, and a copy be furnished for publication to the *Quincy Daily Ledger*, *Quincy Monitor*, and the *Boston Medical and Surgical Journal*.

J. WINTHROP SPOONER, President.

JOHN F. WELCH, Secretary.

METEOROLOGICAL RECORD,

For the week ending February 24, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,030: under five years of age 1,149; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 430, acute lung diseases 577, consumption 342, diphtheria and croup 183, measles 61, scarlet fever 48, typhoid fever 31, cerebro-spinal meningitis 29, whooping-cough 28, diarrhoeal diseases 23, erysipelas 17, small-pox 6.

From typhoid fever Chicago 8, Philadelphia and Lowell 4 each, New York and Pittsburg 3 each, Brooklyn 2, Boston, Milwaukee, Worcester, New Bedford, Chelsea and Malden 1 each. From cerebro-spinal meningitis Chicago 7, New York and Brooklyn 6 each, Holyoke 2, Washington, Cleveland, Worcester, Lynn, New Bedford, Chelsea, Pittsfield and Everett 1 each. From whooping-cough New York 9, Philadelphia 7, Chicago 3, Brooklyn and Boston 2 each, Washington, Pittsburg,

Milwaukee, Fall River and Somerville 1 each. From diarrhoeal diseases New York 8, Chicago 6, Philadelphia, Lowell and Cambridge 2 each, Brooklyn, Boston, Washington, Worcester and Marlborough 1 each. From small-pox New York 5, Boston 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending February 17th, the death-rate was 18.7. Deaths reported 3,747; acute diseases of the respiratory organs (London) 340, whooping-cough 133, diphtheria 86, measles 74, scarlet fever 49, diarrhoea 42, fever 29, small-pox (Birmingham 7, Bradford 2, West Ham 1) 10.

The death-rates ranged from 11.2 in Croydon to 27.0 in Wolverhampton; Birmingham 16.9, Bradford 16.5, Burnley 17.8, Hull 18.9, Leeds 17.4, Leicester 16.0, Liverpool 25.4, London 18.6, Manchester 22.2, Newcastle-on-Tyne 18.8, Nottingham 14.9, Portsmouth 17.1, Sheffield 16.8, Sunderland 19.9, West Ham 16.6.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 24, 1894, TO MARCH 2, 1894.

Leave of absence for twenty days, to take effect upon the adjournment of the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894, is granted COLONEL BERNARD J. D. IRWIN, assistant surgeon-general, U. S. A.

A board of medical officers to consist of MAJOR JOSEPH K. CORSON, surgeon; MAJOR WALTER REED, surgeon; CAPTAIN JULIAN M. CABELL, assistant surgeon, is, by direction of the Secretary of War, appointed to meet at the call of the President thereof, at the Army Medical Museum Building, in this city for the examination of FIRST-LIEUT. PHILIP G. WALES, assistant surgeon, to determine his fitness for promotion.

FIRST-LIEUT. WALES will report in person to the President of the Board at such time as he may designate.

By direction of the President, the retirement from active service on the 25th of February, 1894, by operation of law, of CAPTAIN GEORGE T. BEALL, medical storekeeper, under the provisions of the act of Congress, approved June 30, 1882, is announced.

The leave of absence granted CAPTAIN REUBEN L. ROBERTSON, assistant surgeon, U. S. A., is extended one month.

MAJOR JOHN BROOKE, surgeon, U. S. A., retired from active service February 22, 1894.

FIRST-LIEUT. ASHTON B. HEYL, assistant surgeon, relieved from duty at Fort Niobrara, Nebraska, ordered to Columbus Barracks, Ohio, for duty at that depot, on the arrival of FIRST-LIEUT. THOMAS S. BRATTON, assistant surgeon, at Fort Niobrara, Nebraska.

The leave of absence on surgeon's certificate of disability granted MAJOR EDWARD B. MOSELEY, surgeon, U. S. A., is extended one month.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 3, 1894.

RICHARD ASHBIDGE, passed assistant surgeon, dismissed from the Naval Service, February 28, 1894, by the President's approval of the sentence of General Court Martial.

A. G. CABELL, passed assistant surgeon, ordered to the U. S. S. "Michigan."

J. S. SAYRE, passed assistant surgeon, detached from the U. S. S. "Michigan" and ordered to the Naval Hospital, New York.

R. G. BRODERICK, assistant surgeon, detached from the Naval Laboratory and Department of Instruction, and ordered to the Naval Hospital, Mare Island, Cal.

THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

The fourth annual meeting of this Association will be held in Washington, D. C., May 1, 2 and 3, 1894.

This National Organization is composed of medical officers of the U. S. Army, U. S. Navy, National Guard of the United States and the Hospital Marine Service. The afternoon of one day will be set apart for an object lesson from the "Manual of Drill," by the Hospital Corps. The evenings will be given up to social entertainments.

GEO. HENDERSON, *Chairman Com. of Arrangements.*

NICHOLAS SENN, *President.*

EUSTATHIUS CHANCELLOR, *Secretary.*

THE COLORADO STATE MEDICAL SOCIETY.

TO THE MEMBERS OF THE AMERICAN MEDICAL ASSOCIATION.

Members of the American Medical Association are cordially invited by the Colorado State Medical Society to stop over in Denver on returning from the coast and attend the meeting of the Society convening on June 19th and continuing through the 20th and 21st.

Members who expect to return via Denver are invited to correspond with the Secretary, that invitation to participate in the programme and proper entertainment may be arranged.

EDMUND J. H. ROGERS, *President.*

A. STEWART LOBINGIER, *Secretary*, Barth Building, Denver.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held at the Medical Library, No. 19 Boylston Place, on Monday, March 12, 1894, at 8 o'clock, P. M.

Dr. W. F. Whitney: "Circoid Myxoneuroma of the Tongue," illustrated by lantern slides.

Dr. C. W. Townsend: "Mild Forms of Nasal Diphtheria." Discussion opened by Drs. A. L. Mason and J. H. McCollom.

Members are requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., *Secretary.*

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday evening, March 14th, at 8 o'clock, by Dr. John Homans. Subject, "Ovariectomy." Physicians are cordially invited.

RECENT DEATHS.

JOEL SNAVERNS, M.D., M.M.S.S., died in Roxbury, March 1st, aged sixty-five years. He was born in West Roxbury and graduated from Harvard College in the class of 1850, of which he has since been secretary. He received his degree of M.D. from the Medical School in 1854. During the war of the Rebellion he was acting assistant surgeon from May, 1862, to December, 1863, when he was commissioned assistant surgeon of the U. S. Volunteers. In 1864 he was promoted to be surgeon and in 1865 was made Brevet Lieutenant-Colonel for faithful and meritorious service. He had charge of the hospital ships *The New World* and *De Molay* and was for some time post surgeon at Fort Warren in Boston Harbor. Since 1866 he has been in active practice in Roxbury. He was for some years a member of the Boston School Committee and has been actively interested in the work of secret societies, being Medical Examiner-in-Chief of the Royal Arcanum. He has been a Councillor of the Massachusetts Medical Society and President of the Norfolk District Society. He was a man of scholarly habit, keen perception and quiet, unostentatious execution. His literary work was marked by wide research, careful criticism and a clear, attractive style. He won the professional respect as well as friendship of those who were his colleagues.

WILLIAM JOHN GORDON FOGG, M.D., M.M.S.S., died in South Boston, February 27th, aged forty-three years. He graduated from Harvard College in the class of 1873 and from the Medical School in 1876.

JAMES PARRISH, M.D., died in Portsmouth, Va., January 21, 1894. He was a member of the Medical Examining Board and of the State Board of Health of Virginia.

THE TREATMENT OF PREGNANCY COMPLICATED BY HEART DISEASE.¹

BY GEORGE G. SEARS, M.D.,

Physician to Out-Patients, Boston City Hospital.

In reporting the following case I realize that I may lay myself open to severe criticism for hasty action, but I hope to prove that the course adopted was chosen only after full consideration had shown it to be the best method of meeting a complication of pregnancy, whose gravity is universally recognized, but whose treatment seems to have been most inadequately dealt with in the text-books.

The patient was sent to me by Dr. George Haven, in 1889, when she was twenty-one years old, for the relief of cardiac symptoms of over three years' duration. There was no rheumatic history, but she had had both scarlatina and diphtheria as a child. There was little oedema of the feet, considerable dyspnoea on exertion, cough and slight hæmoptysis. The cardiac dulness extended about one finger's breadth to right of sternum, while the apex was in the fifth interspace just within the mamillary line, where a loud presystolic thrill could be heard and felt. She improved greatly under treatment, and after a few weeks discontinued her visits; so that I saw nothing more of her until November, 1892, when she again appeared for advice.

During the intervening three years she had been fairly well; but on several occasions after exercise she had had "fainting spells," which were preceded by severe cardiac pain. During the early part of the summer she had overexerted herself in preparation for her marriage, which took place in August. Her catamenia, which in July were attended by an excessive flow, occurred last on August 27th, since when she has been gradually losing ground, cough and dyspnoea having slowly increased. Hæmoptysis now frequently occurred, vomiting had become very troublesome, and she was very anæmic. Always nervous and somewhat hysterical, her condition had become greatly aggravated by the recent death of a friend during labor, from some cardiac complication, and she was haunted night and day by fear of a similar fate.

The lateral area of cardiac dulness had somewhat extended, as compared with the last examination; and in addition to the presystolic, a short systolic murmur was at times heard a little to the left of the apex beat. Except for oedema of both bases, the lungs were normal, and there was no swelling of the extremities. The urine had a specific gravity of 1.022 and contained a very slight trace of albumen. The pulse was regular but very small and easily compressed. While at rest its rate was only 78, but on the slightest exertion it rose to over 100. Dyspnoea was so great that she spoke only in disjointed phrases, pausing after every few words to catch her breath.

After a month's treatment by rest in bed, a restricted diet, digitalis and tonics, her condition became somewhat better, vomiting grew less frequent, and the pulmonary oedema cleared up; but as the dyspnoea improved but slightly, and the pulse made no gain in strength, I asked Dr. Haven to see her with me.

After a thorough discussion of the case, it was de-

cided to induce abortion; and on December 12th Dr. Haven dilated the cervix and packed the womb with iodoform gauze, this method being chosen in preference to an immediate evacuation as, with her extremely weak pulse, we feared the effects of etherization on the heart. Two days later the packing was removed, and a four months' foetus found in the vagina, the discomfort of the patient having been very slight. Recovery was uneventful, but her later condition has been such as to confirm the wisdom of our action. She is able to come into town occasionally to report, but can walk only at a very slow pace, and has since had several attacks of pulmonary oedema, in which her condition was critical.

To briefly recapitulate, the problem which confronted us was this: a patient with a double mitral lesion, between three and four months pregnant, who has had for several years alarming symptoms of failure of compensation, and in whom the slightest exertion, after a month's careful treatment, upsets the cardiac balance, is called upon, after passing through a further period of five months, during which increased demands are physiologically made on the heart, to meet the tremendous muscular strain of parturition; What advice should be given her? Or rather, to put the question in more general terms, What advice should be given to any pregnant woman with heart disease? Should she be allowed to proceed toward term, her strength being carefully supported and her progress watched with the possibility always in view of terminating pregnancy if her condition becomes desperate, or should she be at once delivered? Mortality statistics drawn from published cases make the outlook for these patients very bad when nature is allowed to take its course; for Porak,² out of 92 cases, found a death-rate of 38.09 per cent.; and Remy,³ out of 118, found one of 33.8 per cent. Of 77 cases collected by Wessner, 38 died, or 37 per cent. As all these series contain a number of identical cases, including McDonald's, a close similarity in the ratios was to be expected. More recently, Schlayer has reported 25 cases with 10 deaths, and Leyden 20 cases with 11 deaths. Of 30 cases which I have collected, not included in the above, 10 died. These percentages are based upon the number of women, not on the number of pregnancies, and are drawn almost entirely from severe cases, and may therefore approximate the average death-rate when serious symptoms have appeared. That they overestimate the actual mortality in the rank and file of cases is proved by every-day clinical experience, which shows that a large proportion of them pass through pregnancy and labor without the development of any evidence of serious cardiac embarrassment, or even at times of any signs whatever which lead the patient to suspect her disability.

One of these seems of sufficient interest to briefly report, not only on account of the number of pregnancies successfully weathered, but also because the ultimate fate of the children corroborates the grave prognosis which is given of their chances of surviving to adult life. The lesion was one of mitral regurgitation and stenosis. The patient, Mrs. C., thirty-two years old, had had three attacks of chorea as a child, but no distinct history of rheumatism. Between the ages of eighteen (when she was married) and twenty-seven she had six children, and one miscarriage at three

¹ Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, January 17, 1894.

² Thèse de Paris, 1880.

³ Thèse de Nancy, 1880.

months. The first pregnancy was uneventful, no trouble being suspected with her heart, but the second was attended by many stormy symptoms. She then received treatment for the cardiac condition and had much less difficulty with the next three, breathlessness and œdema, however, being more or less troublesome in each; but in the sixth her condition was such that the gravest apprehensions were felt as to her recovery, and the last few weeks were spent propped up in a chair. The labors were all rapid and easy, being terminated within an hour. The third child alone survives, the others all dying within a few months after birth.

For the sake of simplifying the original question cases of pregnancy complicated by heart-disease may be divided, with reference to treatment, into three classes, according to the severity of the symptoms: the first including all cases where they are wanting or slight, the second those in which they are so severe that the condition of the patient is desperate, and the third those which occupy a position midway between the two. The treatment of the two former may be dismissed in a few words. In the first, general supervision over the patient's manner of life, with the administration of tonics, will probably be all that is required to bring the case to a successful termination, or, at most, it may be necessary to hasten delivery should danger arise from too prolonged a labor. In the second class, the condition of the patient is already so critical that the induction of abortion may seem to give the only chance, though even here a timely venesection may change the aspect of the case, as it has done in several recorded instances, in one or two of which it was repeated several times. In the third class, to which the first case reported above belongs, as well as most of those in which the statistics previously given are based, where the patient still has several months before her, and symptoms have developed which either do not yield, or only partially so, to appropriate remedies, conditions are much more complex; and the question of treatment, whether by hopelessly waiting for nature to act, or by sacrificing the child in the interest of the mother, can only be decided in an individual case by the most careful study, both of her material circumstances and of her previous history and present physical condition, so far as they bear on the probability of an easy or difficult labor, and the preservation or loss of cardiac compensation. Many of these are fully discussed in text-books on heart disease and midwifery; so that only those need be mentioned in which the two conditions react upon each other, although the advantages of general good health and the ability to command every necessary attention may be referred to, as two such circumstances had considerable influence in determining us to induce abortion. These were the intense anxiety caused by the death of a friend under similar circumstances (which was alone exhausting her strength), and her suburban residence (which prevented prompt medical attendance should it have been suddenly demanded). The following points, however, deserve special consideration, namely, the site and gravity of the lesion, the time at which it was acquired, its stationary or progressive character, the period of the present pregnancy at which serious symptoms developed, and, in multiparæ, the history of previous pregnancies and labors.

As was to be expected when dealing with a class of patients, most of whom are under forty, and all of

whom are women, statistics show that mitral disease largely predominates. Thus, out of Porak's 92 cases, there were 22 instances of mitral regurgitation, with 8 deaths; 13 of mitral stenosis, with 8 deaths; and 22 of combined mitral lesions, with 10 deaths; in all, 57 cases, with 21 deaths. There were 13 cases of aortic lesions, with 8 deaths; while of 22 cases of complex lesions, 11 died. Remy found 29 cases of mitral insufficiency, with 6 deaths; 19 of mitral stenosis, with 11 deaths; and 15 of double mitral lesions, with 6 deaths; a total of 63 cases, with 23 deaths. Of the aortic cases, there were 12 with regurgitation, of whom 2 died; while 2 with stenosis and 3 with a double lesion recovered (17 cases and 2 deaths). Of complex lesions he found 16 instances, with 3 deaths. Of the cases which I have collected, there were 14 of mitral stenosis, with 4 deaths; 1 fatal case of mitral regurgitation; and 2 with combined mitral lesions, both of the latter recovering. There were 6 aortic cases, with 1 death; and 7 of complex lesions, with 4 deaths. If these latter figures be added to those of Remy, as the larger of the two series just quoted, we find the mortality-rate to be as follows: mitral stenosis, 45.5 per cent.; mitral regurgitation, 28.33 per cent.; double mitral lesions, 35.5 per cent.; and complex lesions, 30.5 per cent. The mortality-rate of the pure aortic cases was but 13.67 per cent., but 3 out of 23 dying, in all of which the valve was insufficient.

As these figures are drawn from the same source as those previously given, the same criticism is applicable, that they represent serious cases only, but so far as any conclusion is justifiable, they show that mitral cases are more apt to terminate fatally than aortic of apparently equal severity, and those with mitral stenosis than those with regurgitation, a conclusion which has its value, though a slight one, in estimating the chances of an individual case.

The means of determining the extent of the cardiac lesion are not altered by the advent of pregnancy; but the point was well made by McDonald, that the probability of its being compensated is much enhanced if it is not of very recent origin, for if the muscular substance of the heart has had opportunity to hypertrophy till it is able to counterbalance the valvular defect, it will be much more liable to prove sufficient under the additional strain than when the double duty is thrown upon it all at once. The prognosis is also better if the first appearance of serious symptoms is postponed until the later months; but in estimating their gravity it is essential not to confound those which are due to the cardiac lesion with those which result from the profound impression sometimes produced by an uncomplicated pregnancy upon the maternal organism, and which, though threatening, may be expected to pass off after the third month.

With the development of the uterus and the growth of its contents, coincident changes in the circulatory apparatus take place, and lead to a physiological hypertrophy and dilatation of the heart, while alterations in the composition of the blood induce a form of anæmia and so impair the cardiac nutrition that fatty and other degenerations of the myocardium are not very infrequent. Such changes occur gradually, and are not usually sufficiently pronounced to give rise to symptoms of failing compensation till between the fourth and sixth months; so that, other things being equal, little reserve power in the heart may be inferred

if they appear before that time. The reverse of this proposition, however, that the later the development of symptoms the better the outlook, is only partially true, as cases are occasionally met with where the patient has passed through her pregnancy without exciting any special anxiety, and yet has suddenly died from œdema of the lungs during labor or even in the puerperium. At times, also, death results from post-partum hæmorrhage, a not very infrequent occurrence in these cases, though it is possible that its gravity is often overestimated since it may be a conservative effort of nature, especially in mitral disease, to relieve an over-distended right ventricle.

In multiparæ the histories of their previous experience may give much valuable information, as the tendency of the cardiac symptoms is to grow more severe with each succeeding pregnancy, owing to the extra burdens which have been thrown upon the heart, and also occasionally to fresh attacks of endocarditis, to which pregnant women seem peculiarly liable. But little doubt can exist of the necessity of inducing abortion if there is a history of extreme danger in the previous pregnancy of gravido-cardiac origin, or if, with serious symptoms in the present, the lesion is found to be progressive from a rekindling of the endocardial inflammation. As the period of greatest danger is during the expulsive stage of labor from the participation of the abdominal and other muscles, after the necessity of terminating pregnancy has been once determined, the sooner it is done the greater the chances for the mother, especially if the fœtus is still small and the expulsive force can be chiefly furnished by the uterus. The idea that the induction of labor may be held in reserve until the patient is in a condition of imminent peril and then be resorted to in the anticipation of accomplishing any great measure of relief, does not seem to be justified by facts. Schlayer⁴ says that all cases in which premature labor was brought on under these circumstances in one of the obstetrical clinics of Berlin, died either during labor or shortly after, and in the published cases also recovery followed only in rare instances.

Regarding the moral side of the question it must be admitted that the child is apparently sacrificed for the sake of a mother whose health is permanently impaired and whose expectation of life at best cannot be long, but it is a fair question whether too much importance has not been attached to it, if the ultimate fate of the child be considered, when nature is allowed to take its course. Charpentier says that abortion and premature labor are very frequent and the children who are born at term do not live long. So sweeping a statement cannot, of course, be taken without qualification, otherwise it would be an almost imperative duty to induce abortion at the first sign of danger, but he quotes Casanova as believing that in more than half the cases where more or less marked symptoms have manifested themselves pregnancy is not completed, and says that Duroziez noted twenty-one miscarriages among forty-one women with heart disease, and five deliveries at six months, while thirty-seven of the children who were born alive died before reaching five years.

I cannot refrain from referring to a case of advanced mitral regurgitation which I saw yesterday, as it appears to illustrate so well this point; yet it must be admitted that the fate of the fifth child may have been an

accidental coincidence. The patient was a woman about thirty-six years old, and had been pregnant six times, the first four children being still alive. After the birth of the third child she had an attack of acute rheumatism, from which the cardiac lesion in all probability dates, although no sign of it became manifest until the fifth pregnancy, when she suffered from cough, dyspnoea and other evidence of cardiac embarrassment, but was delivered at term after a very rapid labor. The baby died eighteen months later of some acute pulmonary affection, which was said to be pneumonia. During the sixth pregnancy she suffered from serious symptoms, and miscarried at the seventh month.

There seems to be little question that the mortality-rate among children born after serious cardiac symptoms have developed in the mother, is high, but statistics are meagre, as the child so often passes from observation after the lying-in period is over. The frequency of abortion or premature delivery, however, can be more closely approximated, though the opportunities for error in determining the ratio of this event are great, as in multiparæ it may be impossible to tell when the cardiac lesion first developed, and many of the earlier pregnancies may have been free from any cardiac complication. However this may be, Porak found that out of 214 labors 88 were premature, or 41 per cent.; while Remy, in 272 labors occurring in 112 women, found 87 premature, nearly 82 per cent., 51 taking place before the seventh month.

The fact that the death of the mother has not always occurred in apparently the most desperate cases, has probably had much to do in producing the conservatism which has heretofore prevailed. Yet it is not enough that the patient should come out alive, her future must also be regarded: and when one considers the loss of *morale* induced by the sense of her critical condition, the extra burden thrown by pregnancy upon a weakened heart, and the strain of parturition, so great that in a case of Simpson's rupture of the aorta occurred, it is not surprising to find that child-bearing has been the starting-point in many of these cases of a downward course soon followed by death, which was as much a result of it as though it had occurred before the puerperium was ended, but which, nevertheless, does not appear in the statistics.

I do not wish to be considered as holding a radical position on this question, nor as advocating so serious a measure as an abortion until other means have shown their probable futility, but would protest against allowing moral considerations to drive us into too great conservatism when the danger to the mother is so great and the future of the child so doubtful. I am inclined to believe that when the probable necessity for an abortion begins to be seriously considered, that in the long run we shall have less to regret if it is done immediately than if it is postponed till worse comes to worst under the delusive idea that it is an efficacious measure when employed as a last resort. Certainly after the seventh month, when the child is viable, the condition of the mother should be the chief guide for action.

The question of the advisability of marriage for women with valvular disease has been the subject of much ardent discussion. While it is true that many such patients have passed through numerous pregnancies without apparent harm, yet so many factors have to be considered, for whose estimation we have most insufficient evidence, that except for very unusual

⁴ Quoted in Sem. Méd., March 30, 1892.

cases Peters's dictum seems to be the safest guide, namely, that such women should not marry, that if they are married they should not become mothers, and if they are mothers they should not nurse their children.

The points which I have wished to emphasize may be summarized in the following propositions:

(1) That many women with valvular disease, even when situated at the mitral orifice, pass through repeated pregnancies without the development of serious symptoms, and at times without suspecting that they are victims of such disease.

(2) That as miscarriages are very frequent, and the chances of the child's surviving more than a few years are doubtful, if the mother's condition during pregnancy has been serious, the probable fate of the latter should take so much more prominence in deciding the question of abortion.

(3) That the necessity of inducing abortion is very probable if grave symptoms have appeared during the early months or are present with an advancing lesion, or if there is a history of extreme danger in the preceding pregnancy.

(4) That if the necessity for an abortion becomes apparent, the sooner it is done the better, while the fetus is still small and the expulsive force chiefly furnished by the uterus.

(5) That the hope that relief may be given when the case has become desperate by inducing abortion is delusive, as it is possible that it only increases the danger.

(6) That marriage should be forbidden, except perhaps in very unusual cases, to women suffering from cardiac disease.

SIX CASES OF EXTRA-UTERINE PREGNANCY.¹

ONE A PREGNANCY IN BOTH TUBES AT THE SAME TIME, WITH THE POSSIBILITY OF THERE ALSO BEING A TWIN PREGNANCY IN THE LEFT TUBE. — CELIOTOMY. — RECOVERY IN ALL.

BY F. W. JOHNSON, M.D.,

Visiting Gynecologist, Carney Hospital; Visiting Gynecologist, St. Elizabeth's Hospital.

CASE I. G. F., married, aged twenty-eight, consulted me on Tuesday, September 29, 1891. A diagnosis of extra-uterine pregnancy was made, and I operated on her at the Carney Hospital. The following is the history of the case and the result of the examination:

Dysmenorrhœa since puberty. The pain, situated in front and low down in the abdomen, comes on several days before the flow, and lasts throughout menstruation. For the past year has had quite severe pain in the right ovarian region when unwell. Flows five days. Flows quite freely. Leucorrhœa for years. Had always been regular to the day until August 9th. Instead of menstruating at this time, she went to August 16th, just one week over her time. August 16th flowing began, and continued, at times profusely, for two weeks. In two weeks the flowing again began, and has continued up to the present time. Since August 16th, when the flowing began, until September 20th, has had a dull pain in right ovarian region. The breasts have enlarged.

Sunday, September 20th, was suddenly seized with severe, cutting pain in right ovarian region. This

pain lasted one hour, and produced fainting. This severe pain was repeated September 28th, and lasted two hours. Formerly the pain in the right ovarian region was dull in character, but since the severe attack of pain it has been more cutting in character. From August 9th to August 16th, the week following the date of expected menstruation, there was a dull, heavy dragging-down in lower abdomen.

Examination. — From half-way between umbilicus and pubes, extending over the whole of the lower part of the abdomen, there was marked sensitiveness on pressure. By vagina, a soft mass, the size of the fist, excessively sensitive, was found in Douglas's pouch, and on this the uterus rested in a position of retroversion. Bright red blood flowed from the cervix. Uterus measured three inches in depth. Temperature 99°, pulse 110.

Operation. — On opening the peritoneal cavity, dark-colored blood welled up through the incision. The abdominal cavity below the incision contained fluid and clotted blood of a dark color, and no bright blood was found until the right tube and ovary were brought into view. A portion of the right tube towards the ovary was found dilated. This dilatation was about the size of a small English walnut, and from the upper part of it fresh blood oozed out through an opening the size of a pin's head. The right tube and ovary were ligated and removed. On the left side a cystoma of the ovary was found, and it, with the tube, was ligated and removed. The peritoneal cavity was thoroughly washed out with a salt solution, and the abdomen closed. About a quart of fluid and coagulated blood were removed. The mass in Douglas's pouch was composed of coagulated blood, and was dug out with the fingers. Convalescence was uninterrupted.

Twenty-three days after the operation she was discharged well. December 2d, she reported that she felt perfectly well.

Dr. Whitney's Report. — "The following is the description of the ovaries and tubes from the case of Mrs. G. F., received from you October 1, 1891:

"(1) Ovary and Tube. The portion of the tube measured about six and one-half centimetres. About two centimetres from the fimbriated end, which was normal, was a rounded enlargement measuring about two and one-half centimetres by two centimetres, dark red in color, and covered with shaggy, thin adhesions. About the middle of the nodule, opposite the side of the ligament, was a very small rent with a hemorrhagic, infiltrated edge. The remainder of the tube, about two centimetres, was of normal size and calibre. Sections made through the nodule, and examined microscopically, showed the greater part to be made up of blood clotted among small, villous projections, fibrous in character, and covered with a low epithelium, similar in every way to the villi of an immature placenta. Just beneath the outer surface were large and very thin-walled vascular sinuses. The cavity of the tube was dilated, and its lining membrane was apparently reflected up on to the mass of blood and villi; but whether it was continuous entirely over it could not be determined. Apparently, however, it was not. From the distal end of the nodule there opened a distinct diverticulum from the tube, which could be followed almost to the fimbriated end, where it stopped. The relations were such as to show that the nodule had developed entirely in the main tube, and not in the diverticulum. In none of the sections was there

¹ Read before the Obstetrical Section of the Suffolk District Medical Society, December 28, 1893.

any evidence of a fœtus found. The ovary attached to this tube measured two by two and one-half centimetres, was irregularly shaped, and from one place a reddish nodule projected, which, on section, showed an irregularly festooned outline enclosing a yellow mass of large cells (corpus luteum).

“(2) Tube and ovary. The piece of tube measured about six centimetres, and was of normal size and structure. The ovary measured about three by four centimetres, and was mostly made up of a cyst, filled with thin fluid, extending deeply into the hilus, where there was a layer of ovarian tissue gradually thinning out over the cyst.

“The case is one of tubal pregnancy with rupture. There are no positive data as to the length of time, but from its size it is probably within two months.”

CASE II. B. K., married, aged twenty-eight, entered the hospital September 30, 1892.

Menstruation began at thirteen. Regular every four weeks. (Eleven years ago went three months without menstruation.) Flows five or six days. Flows very freely. No dysmenorrhœa. Three children. No abortion. First confinement October 1, 1889. Last confinement March 1, 1892. Nursed her child up to the time of entering the hospital. She had had a bloody discharge from the vagina for four weeks. This had increased very much since the last of August. Since the flowing began there had been bearing-down pains in the back, side and abdomen. There had been interrupted, sharp pains in the left ovarian region for three weeks. Urine and defecation caused pain in left ovarian region.

Examination showed a large movable tumor on the left side, in the region of the left broad ligament.

Operation, October 10th. On opening the peritoneal cavity, a large, grayish-white cyst presented. Eleven and one-half pounds of dark, bloody-looking fluid were removed by tapping. At the upper part of the cyst inside, there was a solid mass as large as a goose's egg, which was papilloma. Directly opposite this, on the outside of the cyst wall, the mesentery, omentum and intestines were adherent. No papillomatous disease could be seen on intestine or omentum. The pedicle was tied, cut and cauterized. There was an hæmatocele between the layers of the left broad ligament, containing eight to ten ounces of dark, clotted blood and debris. This was emptied, and as much of the broad ligament as possible was tied off and removed. The cavity was washed out with salt solution and packed with sterilized gauze to stop the bleeding, which was quite free. The right tube and ovary looked healthy, and were left. So much shock, lasting for hours, followed the operation that the gauze was not removed for forty-eight hours. In consequence, a sinus was left; otherwise her convalescence was perfect.

Dr. Whitney's Report.—“The specimen consisted of a portion of the tube and ovary, with a considerable mass of dark, clotted blood. The specimen was considerably torn, and the relations were not readily evident to the eye. Microscopical examination showed the tube to be normal wherever seen; but the layers of the ligament were infiltrated with blood, and there were numerous newly-formed vessels and thin-walled sinuses. A few large, flat cells were found mingled with the blood-clot, recalling the so-called decidua cells. A definite diagnosis cannot be made in this case from the histological condition.”

CASE III. H. J. O., married, thirty-eight years of age, was operated on October 17, 1892. Had had three children. One abortion with twins, eight years ago, at five months. Two living children since. Menstruation began at sixteen. Always regular every four weeks. Flows seven to eight days. Always flowed excessively, soaking twenty-five to thirty napkins. Until birth of first child had severe dysmenorrhœa, beginning with the flow and lasting the first day. Since first confinement absolutely free from all pain at menstrual periods. Last child was born November 12, 1891. Good getting-up, except that it took her a long time to get her strength. There was a bloody discharge from the vagina for three weeks after confinement. There had been a great deal of leucorrhœa since marriage. March 6th, four months after confinement, menstruation returned. Flowed eight days. No pain. Flowed profusely. Unwell every five weeks until the menstrual period was due in October. When four days over her time, October 10th, was taken with severe pain in the lower abdomen. Fell to the floor, and was unconscious for several minutes. Large doses of morphine were required to relieve the pain. The face was pale, and she felt faint and was very thirsty. Wednesday, October 12th, she was taken with severe pain in both ovarian regions, and begun to flow. There was but a show, and the pain lasted but five minutes. There was no return at all of a bloody vaginal discharge. Saturday, October 16th, during the evening, she had a return of the severe pain in the lower abdomen. She grew very pale, felt faint, and was thirsty. The pain lasted one hour, although morphine was given twice. Monday, October 17th, during the forenoon, she was seized with severe pain in the lower abdomen. As before, she grew pale, felt faint, and was very thirsty. On the arrival of the family physician, Dr. E. S. Boland, the feet, hands and nose were cold. The face was white, the lips colorless. She was restless, with now and then sighing respiration. Temperature 99°; pulse 120. Dr. Boland made a diagnosis of internal hemorrhage, probably a ruptured extra-uterine pregnancy.

Dr. Fogg saw her in consultation, and agreed with Dr. Boland. I saw her with Dr. Boland a few hours after the onset of the pain and collapse. Reaction had set in. The temperature and pulse were normal. The severe pain in the abdomen had ceased, although there was marked tenderness on pressure over the abdomen below the umbilicus. Resonance was present, but over the right ovarian region there was slight dulness. On the right side, nearly on a line with the umbilicus, there seemed to be a line of resistance, but this was less marked when the patient was etherized. Nothing could account for the symptoms more perfectly than an ruptured extra-uterine pregnancy. She was sent into St. Elizabeth's Hospital, and a coliotomy was done as soon as she reached there. The abdomen was full of blood, fluid in the region about and above the incision, clotted in the lower abdomen and Douglas's pouch. Owing to the dulness over the right ovarian region I expected to find the rupture on the right side; but it took but a minute or two to run the right tube between the thumb and finger, and thus prove that there was no rupture on the right side. On feeling for the left tube, the fingers came in contact with a shaggy mass. On drawing this up to the incision the rupture in the tube was seen, from which was squeezed out an embryo in an unbroken sac filled with clear fluid. It

was a beautiful specimen. The right tube and ovary were not removed. On entering the hospital the temperature was 100°, and the pulse 115. Owing to her very weak condition, no attempt was made to wash out the peritoneal cavity. The clots and fluid blood that could be easily reached were sponged out. No drainage. For hours after the operation, shock demanded constant attention. Her recovery was uninterrupted, and she was discharged twenty days after the operation.

Dr. Whitney's Report. — "The specimen consisted of about six or seven centimetres of the Fallopian tube with the ovary attached, and an embryo about three centimetres long in an unbroken sac filled with clear fluid. About two centimetres from the fimbriated end the tube was dilated into an egg-shaped enlargement about three centimetres in its longest diameter. The free surface was torn, and from this a shaggy tissue infiltrated with blood projected. Microscopic examination showed this to be made up of branching fibrous filaments (chorionic villi). The ovary, to which the end of the tube was slightly adherent, contained a large corpus luteum."

CASE IV. S. F., married, aged twenty-nine, entered the hospital November 20, 1892. Has had seven children, the youngest being six years old. Nine years ago had two miscarriages at about six months. Ten years ago miscarried at eight months. After her first labor had puerperal trouble of some kind, and was in bed seven weeks. From her first pregnancy until six years ago never menstruated, as she was either pregnant or nursing. Since then she has been regular every thirty days. Has flowed two to three days, and the amount has been small. Constant leucorrhœa since her last confinement. Last unwell four months ago. During the first two months of this period had no trouble except "morning sickness." Then came loss of appetite, epigastric pain and constipation. Six weeks ago begun to have attacks of sharp pain in the lower abdomen, chiefly in the left ovarian region. About this time a bloody discharge made up of fluid blood and clots begun from the vagina. The abdomen was distended, and everywhere below the umbilicus it was sensitive to pressure. Pulse and temperature were elevated. She had lost much flesh and strength. By vagina, a soft elastic mass, the size of a small orange, was felt in the right ovarian region. On opening the peritoneum dark-colored blood welled up. There was a large quantity of fluid blood and clots in the abdominal cavity, but it was dark-colored. On pressing the hand down to the right tube, an embryo, head presentation, was grasped, and drawn out of a rent in the tube. When placed on the table, it moved. Both tubes and ovaries were removed. The peritoneal cavity was thoroughly washed out with a salt solution. No drainage. She made a good recovery.

Dr. Whitney's Report. — "The specimen consisted of both ovaries and tubes. The right tube measured about ten centimetres in length. The outer eight centimetres of this was occupied by a flattened oval enlargement about six centimetres in diameter. On the free border there was a small opening with a hæmorrhagic, infiltrated edge connected with an irregular rent (made by the finger at the time of operation). This opened into a cavity lined by a smooth membrane. Microscopic examination showed the lumen of the uterine end of the tube partially closed by a fibrous mesh-work, the partitions of which were covered on

either side by a layer of columnar epithelium. The enlarged part of the tube showed villi of the chorion mixed with blood-clot. The embryo which came with this measured seven and five-tenths centimetres. The ovary connected with this measured two centimetres, contained a small dark cyst, and a large corpus luteum. The other tube and ovary showed little change from the normal."

CASE V. W. W. R., married, aged twenty-four, was sent to me by Dr. J. F. Croston, of Haverhill, January 24, 1893. The following is the history of the case:

Never pregnant. Menstruation began at thirteen. Regular every five weeks. Flows seven days. Flows moderately. Never any dysmenorrhœa. September 11th menstruation began, but the quantity was less than usual. Seven weeks after this menstrual period she was seized with severe, excruciating pain in the lower part of the abdomen, in the median line, extending through to the back, and vomiting. The pain lasted one hour. In two weeks the pain and vomiting returned, and lasted two hours. Between these attacks there was nausea and vomiting, but they were not confined to the morning. The third attack came on ten days after the second. When three months over her time ptalism began, and lasted six weeks. The fourth attack came on twelve days after the third. The fifth attack began seven days after the fourth, and was accompanied with a show. November 26th, pain with flowing. December 3d, began to flow quite freely. Went to bed, and flowed one week. December 10th, severe pain and profuse flowing, followed by collapse. Four weeks later, with no flowing, passed a "cast of the womb." Stayed in bed until January 10th. No flowing since the collapse. Sore feeling in the left ovarian region. If pregnant, would be four plus months. Nausea and vomiting lasted until the cast of the womb came away. Six years ago she was in bed six weeks with peritonitis, and has had several less severe attacks since.

The history of the case was so typical that I made a diagnosis before examining her.

A smooth, elastic tumor was found behind and to the right of the uterus. Uterus was quite firmly fixed. The examination caused considerable pain.

Sunday, January 29th, the abdomen was opened. There was no blood in the abdominal cavity. Between the layers of the right broad ligament there was a tumor the size of an orange. I tried to tie off the ligament so as to remove the tumor intact, but I was unable to get more than half round owing to very thick abdominal walls, and a poor light. A hole was then dug through into the tumor, which contained a foetus, placental tissue, and blood. The cavity in the broad ligament was thoroughly cleaned out with fingers and sponges, then washed out, and packed with gauze to arrest the oozing. The tube had ruptured on the under side, and the ovum, as it grew, made for itself a place between the layers of the broad ligament. A small cystoma was removed from the left side. The tube and ovary in the right side were removed. She returned home in about three weeks. Menstruation returned two months after the operation, and has been regular every four weeks.

The foetus was given to Dr. Whitney, who was present at the operation.

The blood and *débris* had begun to break down, and had so softened the foetus that it was not preserved.

With some difficulty the sex was made out. This would bring the age of the fetus up to about the fourth month.

CASE VI. This is the only case on record, as far as could be found in the literature on the subject, of pregnancy in both tubes at the same time.

Mrs. H., aged thirty-six, entered the Carney Hospital November 16, 1893. No children. Had aborted three times at about two months. There had been an interval of about one year between each abortion. Last abortion two years ago.

Menstruation began at sixteen. Always regular. Flows three to four days. Uses five to six napkins. Only slight discomfort when unwell.

October 25th, having gone six weeks without menstruating, passed a small blood-clot. "Labor" pains were present to a slight degree, being mostly in front. October 27th, had a severe attack of colicky pain in the lower abdomen, obliging her to go to bed. The pain was severest in the right ovarian region and extended up the side under the ribs. This pain was relieved by applications of heat. There was slight flowing. October 28th, she was up and about. October 29th, the severe pain again returned, and she was obliged to stay in bed until November 1st. During this time she was in constant pain. On getting up November 1st, she was seized with severe colicky pains in the lower abdomen and fainted. At this time she began to flow quite freely, and had a "pressing-down" feeling in the rectum. From this time until November 16th she was in bed. The pain was less, but at times it was severe and of a colicky nature. Examination showed an enlarged uterus (four inches in depth), chronic endometritis, a smooth elastic mass in the left ovarian region, and a soft boggy feeling mass in the right ovarian region.

Operation.—The uterus was first thoroughly curetted. About one-half pint of dark-colored fluid blood was found in the peritoneal cavity. On the right side a ruptured tubal pregnancy was found, and it was from this rupture that the hemorrhage had taken place. The dilatation of the tube was at the fimbriated end. On the left side the fimbriated end of the tube was occupied by another extra-uterine foetation. This was removed unruptured. Both tubes and ovaries were ligated and removed. The abdominal cavity was thoroughly washed out. No drainage. Her convalescence was uneventful.

Dr. Whitney's Report.—"The specimen from the case of Mrs. H., removed by you at the Carney Hospital, November 21, 1893, consisted of a portion of both Fallopian tubes with the ovaries attached.

"(1) Right tube and ovary.

"Tube. A piece about five centimetres long had been removed. This was about normal for one centimetre from the cut end, when it suddenly enlarged to a dark-red, egg-shaped mass, four by three centimetres in diameter. The fimbriated end was drawn up against the swelling and spread out upon its surface. There was no free blood coming from it. The surface of the mass was marked by small, arborescent, injected blood-vessels, and was more or less covered by a thin layer of dark, coagulated blood.

"The right ovary measured four by two centimetres, was flattened and very much corrugated, and covered on the surface by thin, quite adherent blood coagula. At the end nearest the fimbriated end of the tube was a yellow opaque body with a more or less convoluted

outline. This measured about one centimetre in diameter.

"Microscopic examination showed that the blood-clot contained thread-like masses, which were evidently villi of a chorion.

"(2) The left tube and ovary.

"Tube. About four centimetres had been removed. The cut end was normal, and the tube continued so for about one centimetre, when it dilated into an irregularly rounded mass about two and a half centimetres long by one and a half in diameter. It contracted again just before the fimbriated end, which was normal. The surface of the enlargement showed injected arborescent vessels like the other, and was also roughened by thin adherent coagula. But quite close to the fimbriated end was a rounded projecting clot about one centimetre high, which section showed to be directly continuous with a dark-red mass filling the interior of the tube. Section through the tube showed a small blood-clot in the wall of the tube near the uterine end, which contained numerous small, branching villi, like those of the chorion. This clot was continuous into the cavity of the tube. The clot which projected from the surface was not connected with this one in any way, and was a perfectly independent affair, which had passed entirely through the wall of the tube. In this were structures recalling very poorly-formed chorionic villi.

"The left ovary measured four and a half by two centimetres, and was of the same flattened and corrugated shape as the right. Its surface was also covered with blood-clot and some fibrous adhesions. At the end next the fimbriated end of the tube was a corpus luteum one centimetre in diameter. The other end of the ovary was occupied by a cyst with bloody contents, the size of a small cherry.

"January 5, 1894. Further study of this remarkable specimen is necessary. But as far as the investigation has gone, it shows with certainty the fact of a pregnancy in each tube, with the possibility of their also being a twin pregnancy in the smaller tube. It is probable that the age of the pregnancy in the two tubes is not the same."

(1) The cause of extra-uterine pregnancy seems to be due to an absence of the ciliated epithelium in the tube. This condition allows the spermatozoa to ascend the tube and there meet with the ovum. It also retards the ovum in its downward migrations. This theory will not hold if the modern idea is true, namely, that *normally* impregnation takes place in the tube.

(2) All extra-uterine pregnancies are primarily tubal, the point of rupture and circumstances determining the variety that will be found after the rupture, provided gestation goes on after rupture takes place.

(3) Rupture of the tube takes place when the limit of its expansibility is reached, and this is usually between the second and third months of pregnancy, usually at the second month.

(4) In this class of cases there should be no delay in opening the abdomen.

NEW POTENCIES FOR PERMANGANATE OF POTASH.

Potassium permanganate of potash is fast becoming a popular antidote for all kinds of poisons. Not only is it efficacious against snake-bite and morphine, but now an Alsatian, M. J. Anstal, claims that it acts as an antidote for phosphorus, muscarine, strychnine, colchicine, oil of sassafras and oxalic acid; at least in dogs, rabbits or frogs.

CASES OF EXTRA-UTERINE PREGNANCY, WITH OPERATIONS.

BY J. W. ELLIOT, M.D.

CASE I. Unruptured tubal pregnancy.

This case was reported in part in the *Boston Medical and Surgical Journal*, February 2, 1893, by Dr. Prior, of Malden, with whom I saw it. An abstract is here included to make my report complete.

The patient, aged thirty-five, was married to a second husband. She had had pelvic peritonitis several years before her present illness. She finished a normal menstruation at the end of June, 1891. About six weeks later, at the end of August, she had a show of blood, which lasted a day or two and ceased. This sort of flowing continued intermittently to the end of September. She had the same pain she usually had at regular menstruation, and thought this was simply a prolongation of that process.

She consulted Dr. Prior for a nose-bleed on October 18th. He found the uterus slightly enlarged, and the left Fallopian tube large and tender. One week later the flowing returned. She was put to bed with more pain and a temperature of 100°. There was no nausea.

I saw her, in consultation, on November 1st. There was a boggy swelling in the region of the left tube. The diagnosis was chronic tubal disease, either gonorrhœal or tubercular, with hæmorrhage from the tube coming out through the uterus. Extra-uterine pregnancy was considered and thought less probable.

Operation, November 25th. The abdomen being opened, the pelvic contents were found matted together by old and new adhesions. Both tubes were found inflamed and enlarged, especially at their outer ends, forming with the ovaries the so-called tubo-ovarian cysts. In dissecting out the left side I noticed that it was very vascular; four or five arteries spurted in different directions. When removed, this proved to be the unruptured sac of a tubal pregnancy. The patient made a good recovery.

The following is Dr. Whitney's report on the specimen:

"The specimen consisted of about three inches of the Fallopian tube with an ovary attached. The tube was of normal size and appearance, till close to the fimbriated end, where it suddenly dilated into a round mass about the size of a robin's egg. The color was a dark red, and the surface was slightly roughened.

"Sections made at right angles to the long axis of the tube showed greatly dilated and sinus-like blood-vessels among the clots, in which were portions of chorionic villi; and in the midst of the mass which occupied the centre of the tube an embryo, slightly curved, and measuring about four millimetres in length, which would place it between the eighteenth and twentieth days.

"In the ovary a well-marked corpus luteum with deeply festooned edges."

CASE II. Tubal pregnancy of five months' standing; rupture, causing pelvic peritonitis.

The patient, aged thirty-two, had been married several years, and had had no children. The catamenia had always been regular. In September, 1892, she passed her period, and had occasional nausea in the morning during the last of the month. Two or three weeks later she had an attack of pain in the abdomen, with flowing, and went to bed. After a fit of coughing a membrane came away from the vagina. The

flowing continued through October, and in November she had an attack of pain and tenderness in the abdomen. During December she felt somewhat better, but still had slight flowing and pain.

She entered the Massachusetts General Hospital January 30, 1893. She was well nourished, fat and ruddy. On examination, a tender, fluctuating mass was found on the right side of the uterus extending down into Douglas's fossa. There was also a smaller mass on the left side.

Operation, February 6th. The patient was placed in the Trendelenberg position. When the abdomen was opened, the pelvic cavity was found walled off from the general peritoneal cavity by old and new adhesions. When opened, it was found full of dark, clotted blood, with a quantity of shreddy, placental-looking tissue. The right ovary and tube dilated, tortuous and ruptured, was tied off and removed. The left tube, being diseased, was also removed. The pelvis was sponged out, and the abdomen closed with a glass drainage-tube in the pelvis. The patient made a rapid recovery.

Unfortunately, I have been unable to find the pathological report on this specimen, but have a record from the hospital, that it was evidently a case of ruptured tubal pregnancy of several months' standing.

CASE III. Tubal pregnancy; sudden rupture, with alarming symptoms and collapse.

The patient, aged thirty-two, was unmarried, but was exposed in the last of December, 1893, about one week after the cessation of a period. She then went five weeks without any menstruation. A flow then began, which continued each day for three weeks, and was always preceded by pain.

On February 11th Dr. Lena Ingraham examined the patient at her office, and made a diagnosis of extra-uterine pregnancy. The next morning the patient was suddenly taken with weakness and vomiting and a pain in her left side. The pulse became rapid, and she was in a critical condition. She was sent to the Massachusetts General Hospital on February 12th. When seen there she was pale, with sunken eyes and a bad expression. The abdomen was swollen and tympanitic, and slight pressure caused pain. The uterus was enlarged, and there was a fulness in Douglas's fossa. During the night she vomited frequently, and the abdominal tenderness and distention increased, but the pulse improved. February 13th, the patient looked badly, being of a yellowish-white color.

The operation was done in the Trendelenberg position. The abdomen was found full of black clotted blood. The bleeding came from the right tube, which was markedly dilated. The ovarian artery was enlarged. In the clots removed from the pelvis there was a little sac the size of a bean, which looked like an embryo, (unfortunately this was not examined microscopically). Both tubes and ovaries were removed. The abdomen was sponged out, and a glass drainage-tube placed in the pelvis.

The patient rallied from the operation, and made a slow recovery. One year after the operation she was found to be in excellent health.

The following is Dr. Whitney's report on the tubes removed: "The specimen consisted of both tubes and ovaries, and a mass of blood-clot, at one part of which was a more or less shaggy membranous patch. One tube and ovary presented nothing markedly abnormal. The other ovary had a portion torn away from it,

which on section was found to be a corpus luteum. The tube was thickened and dilated towards the fimbriated end. In the walls there were no greatly dilated blood-vessels or hæmorrhagic infiltration. The section through the clot showed masses of well-marked chorionic villi.

"Although there is no absolute microscopic evidence that the conception had taken place in the tube, still it is probable that the ovum developed there to a degree and then an abortion took place into the abdominal cavity, sufficient time having elapsed to allow retrograde changes to have taken place in the tube."

CASE IV. Tubal pregnancy; rupture, with serious symptoms.

The patient, aged thirty, entered the Massachusetts General Hospital in November, 1893. She had had two children, the youngest being six years old. Her catamenia had continued regularly throughout her second pregnancy. From that time on there had been no irregularity. The month before entrance the regular flow had been much more profuse than usual, and had been accompanied with darting, cutting pains in the lower abdomen. This pain had recurred every three to four days since that time. The week before coming to the hospital the pain had become very severe, and the uterus had been curetted. Catheterization then became necessary. She had had occasional slight chills, one quite severe. She thought herself three months' pregnant, and had cravings and a great appetite.

On examination the uterus was found to be somewhat enlarged, and there was a tender mass, the size of a fist, in Douglas's fossa. On the following day this mass was found to have filled the pelvis and to have extended nearly up to the umbilicus. The patient was suffering great pain, had a poor pulse and a very bad general expression. As Dr. Warren, in whose wards she was, happened to be out of town, I operated at once, fearing that any delay might be fatal.

The patient being placed in the Trendelenberg position the abdomen was opened by a large incision. The whole pelvis and lower third of the abdominal cavity was full of dark, clotted blood. This hæmatocele was walled off from the rest of the abdominal cavity by recent adhesions; the enlarged, flattened and much displaced uterus formed a part of this barrier. The adhesions were separated and the blood scooped out. The right tube, enlarged to the size of a lemon, and containing a mass of tissue and clotted blood had been ruptured. The other tube showed the effects of chronic salpingitis. They were both removed. The ligated pedicles were markedly oedematous. The blood cavity was sponged out, and the abdomen closed without drainage. The patient made a good recovery.

Dr. Whitney's Report.—"Specimen consisted of about fourteen centimetres of the Fallopian tube, with part of the ovary attached; two centimetres of this were of normal size, then dilated suddenly into an elongated sac about three centimetres in greatest diameter, and then contracted again at about two centimetres from the fimbriated end, which was quite open. In the dilated part of the tube was a firm, dark-red mass interspersed with whitish, fibrous-looking things, and in the centre a cavity, one centimetre in diameter, lined with a smooth membrane. This mass was adherent at the part next the normal tube, and was only slightly attached elsewhere; it was directly continuous with a clot the size of the end of the thumb protruding from the rent in the tube opposite the line of attachment of

the tube and close to where it commenced to contract again at the fimbriated end. There was no blood found in this part of the tube. Microscopic examination showed the white strings to be made up of branching and club-shaped villi of the chorion. No remains of an embryo were found. Tubal pregnancy, with rupture."

CASE V. Probable tubal pregnancy; rupture, with sudden and alarming symptoms.

The patient, aged thirty-seven, gave the following history: She had one child fourteen months old. Since the birth of the child she had been regular until four months before I saw her, since which time the monthly flow had not appeared. She had a large appetite and the breasts were large and tender; she therefore supposed that she was pregnant. One month before I saw her, she was taken with sudden and severe pain in the lower abdomen, and with vomiting; while kindling the fire she fell on the floor in a faint. After this she remained in bed for a week or ten days, suffering much pain. When she got up she had a heavy and sore feeling in the lower abdomen, and there was an irregular, bloody discharge from the vagina.

The night before I saw her, she had another attack like the one just described. She again fainted, with sudden severe pain in the epigastrium; there was also vomiting and diarrhoea. Dr. F. B. Lund saw her, and considering it a case of extra-uterine hæmorrhage, sent her to the Massachusetts General Hospital, where I saw her and operated a few hours later.

On entrance the patient had a yellowish-white color; was languid and sluggish in her movements; and could not talk intelligently. She had the look of a person in a critical condition, although the pulse and temperature were about 100.

When the abdomen was opened, the pelvis was found to be filled with an hæmatocele, which had ruptured (causing the second attack of pains) and was filling the abdominal cavity with blood. About a quart and a half of blood was scooped and washed out of the pelvis and abdomen. Fresh bleeding was seen coming from the region of the right tube. Both ovaries and tubes were involved in the adhesions of the hæmatocele, and were therefore removed. The abdomen was closed without drainage. The operation was quickly finished, and the patient suffered no shock; a large amount of salt solution was given by rectum. The patient made a slow recovery, convalescence being interrupted by a pelvic abscess.

Dr. Whitney has not finished the report on the specimen.

IMPURE ICE.¹

BY F. A. DUNBAR, M.D., CAMBRIDGE, MASS.

DURING the past year my attention has been drawn to the purity, or rather impurity, of the ice supplied in this city, and I have made quite a number of analyses of ice taken from the ice-wagons while they were delivering to customers their daily supply, as well as from the ice stored in the ice-houses. I have also looked over the sources of supply of many of the companies who cut ice near by, and as the results of these examinations have been quite interesting to me, I thought the Society might be interested by a short account of the present condition of ice as supplied here for domestic use.

¹ Read before the Cambridge Society for Medical Improvement.

when the bacteria themselves may be destroyed, it is probable that their spores may be more resistant than the bacilli to cold, just as they are to heat. Cases of typhoid fever, as we all know, are most numerous in the fall; and some epidemics have already been traced to the use of water contaminated by previous cases.

It does not require a great stretch of the imagination to suppose a small pond contaminated in the late fall or early winter by the washing into it of typhoid discharges from cases occurring on its banks. If this pond should shortly after freeze over, it does not seem beyond the bounds of possibility that the ice cut from it might give rise to fresh cases. I do not know that any cases of typhoid or other diseases have been traced directly to the use of impure ice, and indeed the difficulties in the way would be so great that it may never be done; but it seems to me that until we have fewer cases of infectious diseases, for which we can ascribe no cause, the chance of some of them originating from the ice-supply should not be ignored, and if it is considered necessary for a town to have a pure water-supply, the source of its ice should no longer be left to chance.

The State Board of Health have made an investigation into the condition of the ice-supply throughout the State (an account of which may be found in the report of 1890), and have also made numerous experiments to see how far water could purify itself by freezing. These experiments resulted somewhat as follows:

Different parts of the same cake of ice may differ greatly in purity; the snow-ice is always the most impure; and of the clear ice, the more air-bubbles it contains, the more impure the ice is found to be; moreover, the bacteria are found to be far more numerous in snow-ice and around a layer of air-bubbles in clear ice. When a pond freezes over, the first inch of ice seems to be about as impure as the water; if snow falls on the ice so as to sink it, and then holes are cut so as to flood the snow, as is generally done, this upper layer is found to be as impure as the water, plus whatever impurities the snow may have derived from air. If now the ice forms rapidly underneath, so that few air-bubbles collect, it is found to be much more pure than the water from which it is formed; whatever impurities it contains are largely composed of the matter held in suspension by the water, the matter in solution being more or less completely removed. As a result of the experiments made, the Board concluded that while clear ice from polluted sources may contain so small a proportion of impurities as not to be considered injurious to health, the snow-ice—and any ice, however clear, formed by flooding—is likely to contain so large a percentage of the impurities of its source, together with some of the disease germs that may be in its source, that no ice can be recommended for domestic use that is cut from a source which would not be considered as suitable for drinking-water.

When one comes to the question of how best to prevent the use of impure ice, and what legal restrictions have been put upon its sale, it is found that scarcely anything has been done in this respect.

There is a statute, passed some years ago, to the effect that if twenty-five consumers of ice supplied by one dealer, and cut in this State, think the ice unfit for use, they may ask the State Board of Health to investigate the matter. The Board may then order a hearing, and put whatever restrictions may seem necessary on the sale of such ice. If the ice-dealer feels

aggrieved, he may take the matter into court and have it tried before a jury. Dr. Abbott, the Secretary of the State Board of Health, tells me that only one such complaint has ever been brought before the Board; and this one was brought by an ice-dealer in order to enable him to break a contract.

There is also a city ordinance on this subject, to the effect that all persons intending to sell ice for domestic use must give notice to the Inspector of Milk some time during the month of April of each year, together with information as to the source of the ice. A penalty of twenty dollars is imposed for non-compliance with this order. The inspector is then directed to make such analyses and examinations of the ice and its source as he may deem necessary, in order to determine its purity, and to give copies of such analyses to the Board of Health and the City Clerk, the latter to be kept open for public inspection. This gives no one the power to prevent the sale of ice, however impure; probably not one person out of one hundred knows that ice analyses can be seen at the City Hall; and even if it were known, not one person out of one hundred would, after looking at them, be any the wiser. As a matter of fact, no one has ever asked to see them. This is not a very good showing, either for the public interest in the matter of impure ice, or for the means at hand to prevent its sale.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

(Concluded from No. 10, page 244.)

CYSTICERCI IN THE SKIN OF MAN.

LEWIN's article on *cysticercus cellulose*, in Eulenberg's "Real-Encyklopädie," has remained up to the present time the most complete exposition of the subject that we have. In the *Archiv. für Dermatologie und Syphilis*, Heft 1 and 2 for 1894, he again takes up the pen on this subject. He repeats what he has previously said, that cysticerci in the skin often simulate tumors of a different nature, for example, gummata, and are not always recognized. He also asserts that few cases have been recorded where the recognition of the *cysticercus* in the skin has made the diagnosis of the parasite in other organs possible, although he has had numerous instances of this in his own practice. His cases, which are described in this article, he divides into (1) those in which the cysticerci cause little or no local disturbance; (2) those which have been taken for gummata, and treated by antisyphilitic remedies; (3) those which also caused disturbances of other tissues or organs, especially of the brain, and which have been considered of syphilitic origin also.

Lewin concludes, from his historical researches, that from the discovery of the *cysticercus* down to 1875, namely, during two centuries, it was only found eight times in the living subject. Since 1875, about 50 cases have been published, yet this number falls below its actual occurrence.

The eggs of the tapeworm inhabiting the small intestine contain the numerous embryos of the future *cysticercus*. The infection of man with these embryos may take place directly through the eggs of the tænia of his own intestine, or indirectly through the eggs of

a tapeworm belonging to another person, although the direct mode is denied by Virchow.

The comparative infrequency of the discovery of cysticerci in the skin is partially due to the slight symptoms caused, which do not lead the patients to seek medical help. Symptoms do, however, occur, but their appearance is very gradual. They may cause more or less severe rheumatic pain, sometimes even suggesting the paroxysms of gout, or numbness or neuralgic pain, stiffness of the affected part, etc.; sometimes there are also inflammatory appearances. These are indicated by pallor, or sometimes a dark brown color of the affected tissue, and capillary hæmorrhages. This inflammation may result in abscess; but whether the suppuration is caused by organisms transported by the cysticercus, or by ptomaines produced by the parasite, can only be conjectured.

With regard to diagnosis, the tumor formed by the cysticercus surrounded by its connective-tissue capsule is always more or less *movable*. The degree of this depends upon the depth of its location, and whether it is fastened by fibres from an adjacent muscle. The nodule is sometimes prominent, often not. The size is variable. On the average they are from a lentil to a hazel-nut in size. It is either round or oval in shape, the former especially in those lying in the subcutaneous tissue, the latter in those contained in the muscles. The consistency of the tumors is characteristic, being almost as hard as cartilage, and in this way it is distinguished from syphilitic gummata. Its surface is smooth. The parasite appears in man both singly and in great numbers. In most instances, there are at least several. The extirpation of the tumors is the decisive test. The bladder-like covering is seen, with a firm, whitish, round body, the size of a pin's head, in its interior, the embryo itself.

Cysticerci may be confounded with tumors of various kinds. Gummata, however, are most frequently diagnosticated, and several cases are related of tumors in syphilitic subjects, which were at first taken for gummata and afterwards proved to be cysticerci. In some cases the differential diagnosis may be extremely difficult, if not impossible. The writer believes that many of the cases of intractable gummata may have been cysticerci, and mentions the fact that Hebra describes no case of the disease in 80,000 cases of skin affections, and makes no mention of it in his work on dermatology. The hand-books on pathological anatomy also accord it scant recognition.

The recognition of the cysticercus in the skin is often of great importance in the diagnosis and treatment of diseases of the internal organs. Sometimes it occurs both in the skin and in the viscera, and its discovery in the former will often lead to its diagnosis in the latter situation. This is especially true of cysticercus of the brain, which is comparatively common, as statistics show, and which cannot be diagnosticated unless cysticerci are found externally. A number of such instances are related.

A cysticercus in the eye is naturally of equal importance in the diagnosis of visceral troubles. Von Gräfe was the first who made this diagnosis, followed later by others.

HIDROCYSTOMA.⁵

In 1884, in a paper upon malaria and sudamina, Dr. Robinson described a peculiar affection, seen especially

⁵ A. R. Robinson: Journal of Cutaneous and Genito-Urinary Diseases, August, 1893.

upon the faces of washerwomen and those who perspire freely upon the face, which was evidently related in its anatomy to the sweat-glands. The affection was described, in his manual of dermatology, under the heading "Sudamina," but has been since referred to by Jackson and others as "dysidrosis."

Robinson has found the affection of not infrequent occurrence in New York City, as he has seen not less than thirty or forty cases since 1884. All these cases, with one exception, have been in women of middle age or older, although he can give no reason for this restriction. In one case it occurred in a young man of twenty-eight, on the lower half of the right side of the nose. Most of the women had been "doing general housework," and most of them attributed it to washing; although some did very little of this work. It occurred also in cooks who did not wash, and in people who neither cooked nor washed; but in the majority of cases the subjects were middle-aged women who perspired freely and did considerable washing over tubs. The cases were all worse in summer than in winter, and in some the affection almost entirely disappeared in cold weather. The lower part of the forehead, orbital region, the nose and cheeks, are the favorite seats of the eruption. The lesions are either discrete or situated closely together, and are "tense, clear, shiny vesicles, obtuse, round or ovoid in form and varying in size from that of a pin's head to that of a pea." They are rather deeply seated and project somewhat above the level of the skin. The smaller ones look like boiled sago-grains, the larger have a dark bluish tint. There are no signs of inflammation. The subjective symptoms are slight or wanting. These vesicles contain a perfectly clear fluid, which never becomes turbid, and is of a slightly acid reaction. The lesion, if unruptured, dries up and disappears after lasting from one to several weeks.

A careful microscopical examination of a number of these lesions showed them to be due to a cystic dilatation of the sweat-duct within the corium. The epidermis was not concerned in the process. A cyst is found in the corium, whose connection with an excretory sweat-duct may be verified by the sections. As the vesicles always contain a clear acid fluid resembling sweat, and as the connection between these cysts and the sweat-duct may be traced, we have here a proof that the theory that the sweat-glands are only fat-producing and not sweat-producing glands, is not true.

Robinson is not able to explain why the lesions form, but he assumes that there must be some abnormal condition in the excretory tube, or surrounding connective-tissue, causing obstruction to the outflow of sweat.

The word sudamen has been used to describe the condition caused by retention of sweat within the corneous layer of the epidermis. This condition rarely appears on the face and is very superficial. As in sudamen the sweat is not retained within an excretory duct, and as in the disease that has been described there is a proliferation of epithelial cells so marked as to cover the whole inner lining of the cyst formed by dilatation, Robinson considers that it is entitled to a distinct name and proposes the term "hidrocystoma" as unobjectionable and fairly descriptive.

The term "dysidrosis" that has been applied to this condition is deplored, as tending to confuse it with the dysidrosis of Fox and Hutchinson, or pompholyx,

rich is an acute inflammatory affection occurring on the palms and soles.

THE TREATMENT OF CERTAIN SKIN AFFECTIONS BY THYROID FEEDING.

In the Dermatological Section of the British Medical Association held at Newcastle-on-Tyne, August 2, 1893, Dr. A. T. Davies read a paper on the above subject, which is printed in the *British Journal of Dermatology* for September, 1893.

It has been noticed that when the thyroid gland is given medicinally in myxœdema, the skin and glands regain their normal condition and there is a new growth of hair. In illustration of the influence of thyroid feeding on the skin, a case is cited that was shown at the Hunterian Society in April, 1893. The woman had, by accident, taken ten thyroids at once. The result was an acute dermatitis, with a "peculiar sticky secretion," followed by peeling of the entire hands.

The following four cases of skin disease were treated by Davies with tablets of thyroid extract :

CASE I. A blacksmith, suffering from psoriasis, which had begun three weeks previously on his left arm and had gradually affected the rest of the body. One tablet of thyroid extract a day was given, and the improvement was immediate. In eight weeks the patient was cured. He had taken, before the thyroid extract, a simple alkaline tonic for three weeks, which had had no effect upon the skin. There has been no relapse.

CASE II. A boy of sixteen, with psoriasis of three years' duration. This patient had been for some time using chrysophanic acid externally and taking arsenic internally, but in April, was put on thyroid tablets also. There was so marked an improvement after the thyroid was added, that the arsenic and chrysophanic acid were discontinued. After taking the tablets for three months he was practically cured.

CASE III. A woman of forty-three, with ichthyosis; which is congenital, and other members of her family are affected. After taking a thyroid tablet every day for a month, she was very much improved. At first the desquamation was increased, but soon began to diminish, and the skin generally to assume a more natural condition. Perspiration of face and head has also increased.

CASE IV. A woman of fifty-nine, who had had a chronic eczema for twelve years, with acute exacerbations, and who had been treated by Davies for seven years. During the last acute attack one thyroid tablet a day was given in conjunction with the other remedies, and the improvement was much faster than it had ever been before. Davies concludes that thyroid extract has a powerful effect in altering the condition of the skin, and hence of assisting the action of the remedies used.

At the same meeting Dr. Byrom Bramwell presented a paper on the "Value of Thyroid Feeding in Psoriasis and Skin Affections," illustrated by photographs of the cases. Seven cases had been treated, and there had been great improvement in all but two.

A CHAIR OF PUBLIC HEALTH AT EDINBURGH. — The University of Edinburgh has recently established a chair of public health with an endowment of five thousand pounds.

Reports of Societies.

OBSTETRICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

G. H. WASHBURN, M.D., SECRETARY.

REGULAR Meeting, Thursday, December 28, 1893, DR. EDWARD REYNOLDS in the chair.

Dr. F. W. Johnson made a report of

SIX CASES OF EXTRA-UTERINE PREGNANCY.¹

DR. W. F. WHITNEY: These cases of Dr. Johnson's are most interesting and he has kindly placed them at my disposal for microscopic examination. With one exception there was no doubt of the diagnosis. In the others there were evidences of the fœtus itself or the chorionic villi which showed them to be cases of tubal pregnancy. As regards the case of double pregnancy, there is an abstract of one in the *Gynecological Centralblatt*, in which, however, the account is not perfectly clear that it is of pregnancy occurring in both tubes. So that as far as the literature goes, throwing out this possible double case, Dr. Johnson's statement that his is unique, is correct.

DR. E. W. CUSHING: I think we have to thank the reader of this paper for the very lucid exposition of the subject. It is a pleasure to listen to it as a paper apart from the facts, and the facts are of such great importance that I sincerely hope they will receive the attention from the profession in general which they deserve. It has often been said to me by my friends in Philadelphia, "What are the men of Boston doing that they do not have more extra-uterine pregnancies reported?" There is hardly a meeting of the Philadelphia Obstetrical Society but one or two are reported. There is no great reason to suppose that more cases occur in Philadelphia in proportion to the population than occur in a city like Boston. The inference is that there are many in this part of the country which are not diagnosed and not operated upon, and which die unrelieved. Dr. Johnson evidently is doing his share; and if all the practitioners in all parts of the State, or in this part of the State, would find them as readily, and report them, and get them operated on, I think we should see a good many more.

My own experience is comparatively limited. I have had in years gone by several cases of what we then called hæmatocele, which I have no doubt now were really extra-uterine pregnancies. In 1887 I had and reported a case which was not operated on, but got well without operation. It came very near my household, and attracted my attention very much to this subject. The lady was taken in the theatre suddenly with pain and collapse; got home with difficulty; went from one collapse into another; and nearly died after various attacks of severe pain in the side. Nevertheless convalescence occurred, with slight elevation of temperature, and formation of a collection of fluid in the left iliac region. Dr. Fitz thought that the mass which formed at that time was a serous cyst. On the strength of that case I went into the Museum at Harvard, and picked out every specimen there. These I photographed, with Dr. M. B. Parker, and published in the *Annals of Gynecology*, February, 1888. Since then I have been in the way of seeing and publishing a good many cases; and, as far as I

¹ See page 256 of the Journal.

have been able, I have continually turned attention to this question.

In regard to the escape at the end of the tube, I remember distinctly at least two of Price's cases where the blood was escaping from the end of the tube in large amount.

My own operated cases number three. One, which I have published² was at nine months. I will not devote attention to it here except to say that the placenta there lay in the end of the tube, implying that the tube must have been open at the end and the placenta lay in the middle of it. That was done in Peabody two years ago, and the woman made an excellent recovery. I have had two other cases. One was brought to me by Dr. Galvin, where the principal symptoms were supposed to be probably caused by a pus-tube, namely, pain and high temperature; there was a skipping of the menstruation, irregular hæmorrhages; and it is not always easy to make a diagnosis in such cases. On opening the abdomen blood was not free, but was encapsulated on the side. Separating the intestines, I got into a mass of blood, and removed a tube, which I have here, and which I presume is an extra-uterine pregnancy, I also removed a number of old clots of blood. The other case was brought to me by Dr. Garceau, Jr., and had been seen by Dr. Chadwick and Dr. Homans. Dr. Homans was to operate on it, but had to go to Chicago; and so the case came to me. It proved to be an extra-uterine pregnancy, and the sac unruptured; but it shows that the contention that H. A. Kelly made before the British Medical Association, namely, that a case could be diagnosed before rupture, at least with great probability, is well founded. I believe Drs. Chadwick and Homans agreed with Dr. Garceau that it was in all probability extra-uterine pregnancy. Of course, if the tube is not ruptured, it is the easiest thing in the world to remove.

The only thing of interest which I should wish to bring up for debate is the question as to the location of this blood. Dr. Johnson reports in one case that it was between the layers of the broad ligament. Dr. Whitney also refers to the same, and I know it is Tait's theory that in the cases which do not die the rupture occurs between the layers of the broad ligament, and that the blood is coagulated there. The pregnancy may go on further; or if the fœtus lives, the broad ligament forms a nest for it, in which it can grow, the layers of the broad ligament being separated. The question is, whether that is so in anything except a very rare number of cases. It is, of course, a very beautiful and ingenious theory; but those who have done a great many of these operations have not found that that condition existed. Price reports that he has never found it so, and at last accounts he had had ninety cases. He says that in all cases, whether the fœtus was big or little, the broad ligament was not separated, but the blood was behind the broad ligament, roofed off by adhesions to the bowels, and was free, or in fact a hæmatocele; that the old division of hæmatocele into that which is in the cavum peritoneale and cavum subperitoneale does not exist in his experience as seen at the operating-table in a large number of cases. Others have told me the same thing. In my own case, where it had gone on to nine months, it was not in the broad ligament; it was free in the abdomen, and the end of the tube was a cup. In those

cases where the symptoms were not those of acute rupture, but those of high fever from the beginning of the deposition of this clot, the blood being firmly coagulated, it was in the same place that you get a collection of pus such as was formerly supposed to be in the folds of the broad ligament; it is now agreed that it is in the tube or leading from the tube. I throw out the question for discussion, whether we are passing through the same change of theory in regard to the location of this mass of blood, and instead of believing that it is between the folds of the broad ligament that we shall recognize the fact that the blood has escaped from the tube, that not all cases bleed to death, that in the cases we used to call hæmatocele the hæmorrhage was a small one. Tait states that if it is between the folds of the broad ligament they may not bleed to death. He implies that if it is free in the cavity, they are sure to bleed to death; but, in point of fact, there may be a little opening, leaking enough to start up a little inflammation; it may roof itself off; and the very tubes in which this occurs are apt to be tubes in which there is adhesion about it. So that you get your collection of blood behind the broad ligament; at any rate, that is where I have found it; and other men have found it there without exception. I would like to ask Dr. Johnson if he feels very sure in regard to the point as to where the blood was located in that case, because it is a matter of urgent debate at present.

DR. JOHNSON: In both those cases where there was what I called hæmatoma in the broad ligament, there was no question about it at all. Seven or eight saw it. There was no blood in Douglas's pouch at all. It was bulging out on both sides of the broad ligament. When I bored through, I bored through cellular tissue. It was in the broad ligament in both cases, and those present agreed with me.

DR. INGRAHAM: I desire to say a few words as to the early symptoms which were observed in my case operated on by Dr. Elliot. A woman, thirty-two, single, came to my office one evening about nine o'clock, and said she was suffering very severe pain in the lower part of the abdomen, and had been flowing profusely for one week. She had been regular in her menstruation up to six weeks before her visit. At this time, six weeks before, the menstrual period was delayed one week; then she began to flow every day about an hour. This, I think, continued about three weeks; then she stopped flowing, and did not flow again until a week before she came to the office. The flow at this time was very profuse, and she was so weak that she could not do her work. On examination, I found a good-sized mass on the left, with the uterus quite a little enlarged and the cervix pushed down. The abdomen was so tender that I could make very slight counter-pressure. I told her to go home and report at once if she had pain or felt faint. I suspected it might be an extra-uterine pregnancy. At seven o'clock the next morning she sent for me. I found she fainted at midnight, when she got up to go to the water-closet, and when she recovered she did not know how long she had been on the floor. She was chilly when she got up, and crept into bed. When I saw her, her pulse was 150, temperature 97°, and she had all the symptoms of collapse. That was Sunday morning. We had no bed vacant in the Vincent Hospital, and I telephoned to Dr. Pratt of the Massachusetts General Hospital. He sent an ambulance, and we moved the woman there. Dr. Elliot

² *Annals of Gynecology and Pædiatry*, January, 1891.

operated the next morning. The abdomen was full of blood. The case was one of extra-uterine pregnancy. I think that such cases should be reported, to impress upon the minds of physicians that the symptoms of collapse from any intra-abdominal hæmorrhage are just the same in the case of hæmorrhage in tubal pregnancy. It is difficult, I think, to make a diagnosis of tubal pregnancy unless one takes into consideration all the circumstances. This young woman was single, and stoutly denied any cause. She had been ill so long, that is, she meant she had suffered severe pain every time she was unwell, she thought she had some tumor, and tried to impress me with this idea. The mass was very soft and doughy. When I examined her the next morning at seven o'clock, I found that the abdomen was dull on percussion in the lower part; there was distinct bagging of the walls of the vagina; and the change from the night before in the relation of parts in the vault of the vagina convinced me there was no question whatever of the trouble.

DR. EDWARD REYNOLDS: The Chair thinks Dr. Ingraham's remarks raise an important point. We hear frequently accurate rules for the diagnosis of extra-uterine pregnancy. The specialist and operator knows there are a very large number of cases in which the diagnosis is determined principally by the operation. I think a great many cases are lost because the general practitioner feels that before turning them in for operation he ought to make a more accurate diagnosis than is in reality possible; and I hope we shall hear something on that point.

DR. J. W. ELLIOT: The case Dr. Ingraham mentions was certainly a very good case and a very good diagnosis. She came to the hospital in the condition Dr. Ingraham describes. The next morning she reacted somewhat. I opened the abdomen in the Trendelenberg position, and found a large amount of blood and a ruptured tube which had ceased bleeding. After washing out the abdomen and taking out all the clots, I put in a drainage-tube, and she made a slow but perfect recovery.

Dr. Johnson's paper interested me very much in various ways. One was that he seemed to have made the diagnosis in four out of six cases; which I think is very encouraging, because when the subject came up a few years ago our ideas were so vague that very few diagnoses were made. As time goes on the diagnosis seems to be easier; in fact, I begin to feel now that it is moderately easy to make in most cases. I do not mean to say there are not extremely difficult cases for diagnosis. In the last year I have operated on three cases and the diagnosis was made in two out of the three. One other case was diagnosed as hæmorrhage from the tube with probable extra-uterine pregnancy, which it was. Another case was of long-standing, and the diagnosis was not made and probably could not be made. The prognosis, also, is much more favorable than we used to think. All of Dr. Johnson's cases got well. The four I mentioned got well. They all should get well, of course, for hæmorrhage is not a disease but an accident, and should get well if the antiseptic precautions are observed. Cases like the one described by Dr. Ingraham, where the hæmorrhage is severe and stops of itself, are wonderfully tolerant of the hæmorrhage as well as of the operation.

The diagnostic point that impresses itself on me most of all, is the pain they have. All the cases that

I have seen have had pain. Pain with collapse and tenderness, even if one cannot feel anything in the vagina, would be sufficient reason for opening the abdomen if there had been the slightest irregularity of menstruation. In the cases where the rupture has taken place, one cannot feel anything by vagina, for there is simply extravasation of blood in every direction. As to the question of whether rupture takes place into the broad ligament or not, I have never had a case where it did; but I have supposed it did, because I have read so many cases described by good observers. I do not see why it should not escape into the broad ligament.

This subject is a very important one and I think every one ought to report the cases they see, so that the community may become familiar with the subject, because it is a kind of malady where lives can be saved by good knowledge and prompt action.

DR. W. L. BURRAGE: I have operated on five cases, all of them since October of last year. My first case was a neglected one, and the blood had gone on to suppuration and septic infection. The case was septic, and the specimens were so disorganized that they were in no condition for pathological examination. The specimens of the other cases are in Dr. Whitney's hands; and he has said with reference to them that in two he has completed the examination, and there is no doubt as to the diagnosis. Of the other two, from the preliminary examination and the gross appearances, he thinks there is little doubt. The cases all got well. The first case I reported before the Alumni Association of the Woman's Hospital in New York last January, and published in the *New York Journal of Gynecology* for May. The second case I saw with Dr. C. W. Townsend, and operated for him afterwards. That case he reported before the Obstetrical Society of Boston; and it was reported in full in the *Medical and Surgical Journal*, November 2d, last. The other cases have not been worked over enough yet for report. In three of the cases I made the diagnosis. In the fourth, extra-uterine pregnancy was thought of, but nothing at all sure; and in the fifth it was quite unexpected.

As regards the situation of the hæmorrhage in my cases, I do not think it was in the broad ligament in any of them. It seemed to me to be behind and encapsulated in some, and in others, free; but, as Dr. Elliot says, I can see no reason why it should not be in the broad ligament.

I quite agree with the other speakers in the importance and gravity of the condition, and that the cases should be operated on as soon as the diagnosis is made. Of course, it is very difficult to make a diagnosis in this affection. Pus-tubes are the principal condition with which it is likely to be confounded, but the operation is generally indicated in either event; and, of course, in the case of acute abdominal emergency, operation is the only thing.

The case in which the diagnosis was not made was a hospital case. The patient was thirty years old, married one year for the second time, mother of four children; catamenia always regular, lasting three days, using four or five napkins; backache constantly, worse at catamenia. Entered the hospital August 15th. In July flowed three weeks, passing a great many clots, and had sharp pains in the left lower abdomen that lasted one-half to one hour at a time. Ever since that time she had had, once or twice every week, rather

bad pains; but in her estimation the pain was secondary in importance to a feeling of prolapse at the vulva. There was a mass in the pelvis on the left side, the size of a closed fist; and I thought more than likely it was a pus-tube. The abdomen was very sore. She complained of bearing-down feelings. She had a bad tear in the cervix and another in the perineum. I found this mass in the pelvis, and advised operation. She consented, and we found extra-uterine foetation of about six weeks. When she went home, I believe she complained bitterly because she still had the feelings of prolapse for which she came in, and thought the right thing had not been done.

DR. W. M. CONANT: Since November, 1893, I have seen seven cases of what I thought were extra-uterine pregnancy. Six of them have been pronounced extra-uterine by the pathologist's report; the other one, which was a fatal case, I supposed without question was extra-uterine. It proved to be a hæmorrhagic condition in the tube with pus. That case at the end of a week developed septic peritonitis, and died. The other six lived, and got well. In four the diagnosis was made before operating. The first case which I saw was sent to me as a simple cyst of the ovary, and I so diagnosed, and operated and found a simple cyst. On the other side, I found something which looked like an extra-uterine pregnancy as large as the thumb. So it proved. The other case, perhaps, ought to have been diagnosed, but was not; it was an unruptured tube, and I have been in the habit, from my own experience and the cases I have been able to collect, of dividing the subject into two heads: those that are acute, (and I agree with Dr. Elliot that in the majority of these acute cases you can readily make the diagnosis); and those in which the tube is not ruptured, and are not acute. The diagnosis oftentimes is not accurately made until it is in the hands of the pathologist. The case I lost presented the symptoms which Dr. Elliot spoke of as being the cases he would operate on without question,—there was irregularity of flow, tenderness and a mass in the pelvis. The last case I had was one in which I very nearly made a mistake. The woman presented all the symptoms of acute rupture. I saw her in consultation about ten days before I operated. She had had two or three previous attacks of sharp pain, relieved by rest in bed and opium. I made an examination, and found a mass which felt much like a pelvic abscess. I think this is the only case in which I have been at all tempted to aspirate in the last three years. She was not in a position to have proper care at home, and I advised immediate removal to the hospital. She waited about ten days, and then entered the hospital. I got a history of more or less continuous flow since my last visit.

I found the mass much enlarged, and at once changed my diagnosis from pus-tube to extra-uterine pregnancy, and advised immediate operation. She had that night another attack of sharp pain, with fresh exudation; and the next morning when we opened the abdomen, the blood was fresh. I can verify the statement Dr. Elliot made, that the blood comes out in spurts, because I felt as if I had torn away a part of the iliac vein. It was not until I got hold of both tubes and applied a clamp, that I could get a look. In this case there was a very speedy recovery, in spite of the fact that at the operation the pulse was at 160. She rallied immediately, and now, two weeks afterwards, she is sitting up. We must remember the possibility of so

profuse hæmorrhage that death may follow from exhaustion.

DR. W. F. WHITNEY: In regard to the bleeding from the end of the tube, I do not wish to lay that down as an absolute fact, that it does not occur. But I have found in some cases, where the ovum is situated at a distance from the fimbriated end, there has been a space perfectly free from blood. In the case Dr. Elliot referred to, I also think there is the possibility of mistaking blood which has gone into the fimbriated end from that which has come out. As to the occurrence of blood or pus in the layers of the broad ligament, I do not see any anatomical reason why it may not occur. Of course, as Dr. Cushing rightly states, a great many of the old hæmatoceles are so walled off by thick layers of fibrin and partly organized tissue that it is difficult always to recognize the difference between that and the true connective-tissue of the broad ligament. I have had one case where, I am positive, the pus entirely surrounded the tube and was entirely beneath the peritoneum.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

HENRY JACKSON, M.D., SECRETARY.

REGULAR Meeting, Wednesday, January 17, 1894,
DR. F. C. SHATTUCK in the chair.

DR. G. G. SEARS read a paper on

PREGNANCY AND HEART DISEASE.¹

DR. GEORGE HAVEN: I had the pleasure of seeing this case with Dr. Sears, and the fact that after a month of care and rest this woman had grown worse instead of better, and that her condition seemed to be a very critical one, led me to think the safest thing was to empty the uterus. It has always seemed to me that where the life of the mother was in imminent danger, the life of the child should be sacrificed. It is, I think, a mistaken idea of humanity to wait until the mother is in the last stages of disease before the operation is undertaken in cases where pregnancy is a serious complication of her trouble. This, I think, is true, not only in cases where the heart may cause the trouble, but also where the trouble is due to kidney disease, or the complication is such as eclampsia occurring in pregnancy, so that I have always considered the better thing to do, where the opinion is very distinct that the life of the mother can be saved by sacrificing the life of the child, to sacrifice the life of the child. I think in this case the after-result proved the wisdom of her delivery.

It seemed to me that, in this case, it was unwise to give ether, and Dr. Sears thought so also. The cervix was rather soft and patulous, and was dilated sufficiently to put in a certain amount of iodoform gauze. The vagina was washed with soap and corrosive beforehand, and gauze introduced into the body of the uterus and the vagina packed with iodoform gauze. This was left in the vagina two days, when, upon removing it, the fœtus and the placenta were found in the vagina. I should prefer this to the introduction of a catheter or any foreign substance of that kind, believing, as I do, it is a much cleaner method and a much

¹ See page 233 of the Journal.

surer method. I have seen cases where catheters have been put in, and left in position forty-eight hours, without any result whatever. I have seen cases where the result was disastrous. They are tied outside, and may lead to septic condition of the uterus which may prove fatal to the mother.

Very little mention is made in any text-book on obstetrics or gynecology which I have seen, about the complication of pregnancy and heart disease; and for that reason Dr. Sears's paper is of peculiar value.

DR. EDWARD REYNOLDS: I wish to speak particularly of the question of interrupting pregnancy or of allowing it to go on, not of the conservative treatment of the heart lesion. I would divide the question, for convenience of discussion, into the three periods of pregnancy; when serious symptoms appear in the first three months, there will always be a strong probability of an ultimate necessity for a resort to interference; but in that period due care must be taken to eliminate the depressing effects of the nausea, salivation and other troubles of early pregnancy; to estimate properly the fact that the first three months of pregnancy is a period of depression of the general health in the majority of cases of normal pregnancy, and that after the woman has passed three or three-and-a-half months her condition normally becomes better, so that if the woman with heart disease can be carried successfully past that period, there is then some prospect of an improvement in her general condition, and from that of better toleration of the heart lesion; remembering what I believe to be the fact, that the question is how full compensation takes place.

In view of the effect of pregnancy upon the normal heart, in which the increase of compensation is necessary to overcome the normal added load, if the serious symptoms first appear in the second three months, I think the prognosis will always be tolerably grave. That is the period of well-being in normal pregnancy. If the heart gives out then, it gives out under a load which must be expected to increase constantly towards the end of pregnancy.

In the third three months I should feel inclined to give the benefit of doubt towards letting the pregnancy go on undisturbed. If the woman has come up to the full six calendar months in tolerably good condition, there must certainly be a good prospect of carrying her to the viability of the child at seven months. After she has reached seven months in anything like good condition she does better, as far as my experience goes, than one would expect. I should be inclined toward conservatism during the last three months.

If it is necessary to interfere with pregnancy in heart disease, a word must be said as to the method. I do not think that it would be wise in cases of heart lesion sufficiently serious to require operation to adopt the method which I should prefer for most other conditions — etherizing and finishing the operation, to the removal of the last atom of the ovum, at a single sitting. I think the method by introduction of a foreign body, and preferably of a strip of iodoform gauze, into the uterus, followed by a tamponade of the vagina, almost invariably works well. A tamponade of the vagina is not sufficient by itself, but with the introduction of a foreign body into the uterus, tamponade of the vagina, in my experience, has always resulted in the favorable and tolerably rapid progress of labor. I remember especially a case I saw a year or more ago with Dr. Folsom, where a woman with a serious heart

difficulty, which rendered etherization distinctly inexpedient, started to miscarry spontaneously at about the sixth month. I inserted a little iodoform gauze, and packed the vagina, and at the end of about twelve hours, there being some labor pains present, and the woman becoming greatly distressed, I removed the packing, and found that the os had dilated so far that it was easy to remove the ovum with the curette without pain to the patient and without ether. Even if labor under such circumstances should become distressing, the fact that there has been a preliminary attempt at the induction of labor would probably render it possible to clean out the uterus with the curette, with a moderate amount of pain, without ether, and much more easily than if there had been no preliminary tamponade.

As to the general principle of the treatment of pregnancy complicated by disease of serious import to the mother, I think that the profession in the past, one and all, its most prominent as well as its less prominent members, have been misled by an undue concern for the prospects of immature foetuses. The history of the profession teems with examples in which, when the question of abortion came up, conservatism has been persisted in until still more threatening symptoms supervened; then the abortion has been undertaken, and both mother and foetus have been lost. I think that when this question comes up, that it is usually not, Shall abortion be done now or at some future time? it is almost always, Shall abortion be done now, or shall pregnancy go on to term? Taking the condition I refer to, cases in which the question is properly before us, in which the symptoms are sufficiently grave to bring up the question whether abortion shall be done, it must be decided whether abortion shall be done early. Abortion done for any serious complication of pregnancy is a very simple and safe matter if it is done early; it is followed by the promptest relief to the condition, so far as that is dependent on pregnancy. Abortion done after the woman is anything that approaches moribund is almost hopeless; and the physician should never shirk the responsibility of doing the operation while the mother is in good condition. I think that when we consider the difference between the value of the life of a woman, mature, occupying a place in society, the mother of children, the wife of a man dependent on her for the comforts of his home; when we compare the value of her life with that of a foetus at three months, which is exposed to especially great danger from the condition of the mother, which, even though it be born, runs a strong risk of never attaining maturity, and in heart disease a risk which is again already compromised by the condition of the mother, — I think, under those circumstances, a serious risk to the life of the mother is of far more importance than the termination of the life of the child.

DR. A. L. MASON: The case of Dr. Sears is very interesting, and I have no doubt his course was wise. It must be easy in such cases to wait too long, as it is in the dangerous vomiting of pregnancy, until the operation is too late. When the question arises whether a woman with heart disease should marry, it sometimes is very difficult to decide that in the negative. The cases Dr. Sears has referred to were probably of a very severe description, because the milder cases of cardiac lesion, in which pregnancy occurs and labor goes off without accident, are not reported, and

there must be very many such. The existence of a murmur, provided that there is a good compensation, and has been for a long time, I should think might frequently be no bar to matrimony. Advice is not always asked in such cases; sometimes it is, and it may be hard to decide. The murmurs, which, perhaps, are congenital, or those with perfectly good compensation of many years' standing, where patients are able to take the usual amount of exercise, and can walk up hill without dyspnoea, must be present in many women who can marry with comparative safety. It seems to me Dr. Sears's statement was a little sweeping. I think he said that women with heart disease should not be allowed to marry; if they married they should not become pregnant, and they should not nurse their children. The question is, what degree of heart disease or what conditions of the heart would be sufficiently grave to oblige us to advise that women should not marry.

DR. REYNOLDS: Although I did not have the pleasure of seeing this case of Dr. Sears, I was consulted about it by Dr. Sears and Dr. Haven shortly before the operation was done; and then, as now, I said that while it is always difficult to judge of a case without seeing it, yet, from the symptoms detailed, I should support abortion in that case.

DR. F. C. SHATTUCK: The paper reminds me strongly of a bit of my own experience. Five years ago I was asked to go out of town to see the wife of a gentleman, the subject of mitral disease. She had one child a few years old, and had had a very alarming time at its birth. She seemed to be so well — I think it was in November or December I saw her — that in the previous spring she had been authorized by her family physician to become pregnant. The murmur was reported as slight, the cardiac condition as comparatively unimportant at that time. When I saw her I think she was four months' pregnant. She had then serious cardiac symptoms. Her husband said they had been distinctly advancing — shortness of breath, inability to walk, etc. The murmurs and the evidences of insufficient compensation were distinct; and it was my opinion, which I expressed, that it was best to terminate the pregnancy. That opinion was based upon the belief that we had to do with an advancing cardiac lesion as far as could be told from the symptoms. This woman was so well the previous spring that her heart lesion was considered trifling. It was not trifling when I saw her. They were extremely anxious to have children, and in this matter other counsels prevailed. Soon after she had an attack of influenza with pneumonia, and miscarried without difficulty. Then she went along pretty well; and a year or two later she became pregnant, went to term, was delivered without very serious trouble, but died within two weeks after the labor from cardiac failure.

To-day I saw a lady with a very bad heart who is said to have had valvular disease all her life, as long as anybody knew anything about it. She is about forty years of age. She has had two children, the youngest twelve, both children born without any great difficulty. The doctor was very much alarmed about her first confinement, but she went through it perfectly well. At her second confinement she had one pain, and that lasted three-quarters of an hour without interruption; otherwise the confinement was uneventful, and the symptoms of failing compensation she now presents are of comparatively recent origin.

THE BOSTON
Medical and Surgical Journal.
THURSDAY, MARCH 15, 1894.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,

ECTOPIC GESTATION.

THE report of a large number of cases of tubal pregnancy occurring in this vicinity¹ brings up the pertinent question whether this peculiar condition is really more frequent now than in years past.

This can be surely answered in the negative, as it is not only from here but from all over the world that a great increase in the number of cases has been recorded. During the past fifteen years, seven hundred and eighty cases have been reported, of which about five hundred occurred within the last four years. This great apparent increase is due simply to the attention which has been directed to the subject (just as in the case of appendicitis) and to aseptic surgery, which has rendered successful abdominal operations possible.

The study of the cases from the clinical and anatomical sides has added much to the certainties of diagnosis, the best line of treatment and points of theoretical interest in the way the ovum acts on the surrounding parts.

The diagnosis is often very difficult, especially in the early stages, when it is all important. But the cardinal points of irregularity of menstruation, in a person previously regular, often with a slight persistent flow from the uterus, one or more attacks of sharp pain and syncope, and a tender swelling on one side of the uterus, are now beginning to be so well understood that fewer cases will be overlooked in the future.

There are but two lines of treatment, either the expectant or operative. The real mortality under the former cannot be surely determined. In a series of two hundred and sixty it was found to be sixty-three per cent.; but from the difficulty of diagnosis we are inclined to think a disproportionate number of fatal cases is always recorded. But even placing it as low as fifty per cent., the patient has then but an equal chance. The statistics from the operated cases are more reliable, as the diagnosis always can be verified.

¹ See pages 286, 290 of the Journal.

In a series of five hundred and fifteen cases there was a mortality of twenty-three per cent., thus showing twice as many recoveries as under the expectant treatment; and, moreover, the period of convalescence is greatly shortened. If the zeal of the operator can be restrained from removing everything in the pelvis when he has it once open under his hand, the chances of future sterility are no worse in one case than the other.

The anatomical study has brought out many interesting facts. The most important to the patient is that the first hæmorrhage is rarely fatal, and if the warning thus given is early heeded, the life can be saved. The bleeding occurs in two ways, either from one of the thin-walled sinuses in the wall of the tube directly into the abdominal cavity, or indirectly, first into the foetal membranes and then through the open fimbriated end of the tube or a hole in its thinned wall into the abdominal cavity. But in none of the cases which we have had an opportunity to examine, now over fifty in number, has the hæmorrhage been from elsewhere than the placental site, about which there was formed no protective thickening of the wall. The rupture directly into the abdominal cavity is naturally the more serious for the patient. When it occurs into the membranes, the death of the foetus results, but this does not prevent a repetition of the hæmorrhage. This is proved from the examination of specimens showing that the period of development of the embryo corresponds to a much earlier date than would be the case if it had lived during the entire time the clinical symptoms had indicated. This shows how irrational any treatment is, which is directed alone to killing the foetus (morphine, electricity); for, granted the death is brought about, there is no proof that the tendency to subsequent hæmorrhage will be stopped.

As yet no satisfactory cause has been found that covers all cases; various theories have been advanced to be abandoned. The first thing that bars the way is our ignorance of the place where the ovum is fecundated in the human species. If, as is generally assumed, this is in the uterus, then the accidental meeting of the vitalizing elements at a point elsewhere is a sufficient explanation. If, on the other hand, this should be shown to occur normally before the uterus is reached, as is the case in some of the lower animals, then a hindrance to the onward passage of the egg will be the best explanation. Under any circumstances a normal mucous membrane will be more favorable for the future development than a diseased one. And the facts bear out this assumption.

The possibility of the migration of the ovum from the ovary of one side into the tube of the other side, has been proved by the cases of tubal pregnancy. The best explanation is that by Hasse, who finds that the ends of the tubes are closely approximated behind the uterus during life in many cases, and not widely separated as they are usually described and figured by the anatomists.

The majority of observers agree that when preg-

nancy occurs in the tube there is very little, if any, decidua formed, and but a minimum hypertrophy of the wall, and in most cases a decided atrophy. The examination of our specimens makes us coincide with this view. At the same time the decidua is formed in the uterus, and it hypertrophies as if the ovum was present there. This has suggested to us that the fecundated ovum exerts a double action on the organism, which may be designated as sympathetic and local. From the former would come the uterine decidua and hypertrophy, the true corpus luteum, and changes in the mammary glands. It acts, no matter where in the body the ovum is vitalized, but by what subtle influence is unknown. Naturally a reflex action of the nervous system would be the first to suggest itself. The second action, which may be regarded as the local one, is shown by the rapid development of vessels at the point where the ovum locates. In the uterus this action has been lost sight of from its association with the other changes due to the sympathetic action. But it comes clearly into the foreground when we study the condition in the tube, for here an atrophy of the wall and adjacent mucous membrane are the associated phenomena, due to the mechanical pressure of the growing ovum, while it is in the blood-vessels alone that there is any indication of a marked increased activity in growth, which may be best classed as a process due to an irritation.

THE BACTERIA OF PERITONITIS.

THE interesting subject of the bacteria associated with peritonitis has received a new and important contribution in a monograph by Drs. Tavel and Lanz, in a recent issue of the *Mitteilungen aus Kliniken und Medicinischen Instituten der Schweiz*.

The authors have given in this report the results of their study of seventy odd cases of inflammation within and about the peritoneum or neighboring organs. But only a part of this number fall within the usual acceptation of the term peritonitis. The material for this study, with the exception of a very few cases, has been obtained at operations in the clinic of Professor Kocher, and has, therefore, the great merit of having been secured intra-vitam, thus excluding the possibility of a post-mortem migration of intestinal bacteria into the peritoneum, a possibility which has been brought forward as an objection to the results of E. Fränkel and Prädöhl in their work on peritonitis.

The cases have been of the most varied character and diverse etiology; but if considered analytically they may be fairly well divided into several groups. In considering the bacteria met with in their examinations we shall only mention those which are recognized as having pathogenic significance, and shall neglect the less important forms of which as many as a half-dozen or more species have been observed occurring together in some cases.

Perhaps the most important class of cases are those in which there is inflammation in or about the vermiform appendix. Of these, nineteen cases were studied,

The results may be given as follows: of seven cases of purulent formation within the appendix, the bacillus coli communis was found in six, the streptococcus in two, and the pneumococcus in one case. None of the cases were sterile. In fifteen cases of peri-appendicitis, the examination of the exudate or abscess showed the presence of the bacillus coli communis in eight; the streptococcus in five; the staphylococcus citreus in one; the pneumococcus in one, and actinomyces in three cases. Two cases were sterile. The number of species found varied in the different cases from one to nine in number. It is interesting to note that the examination in seven cases of the interior of the appendix, where the contents were to be considered as normal or not affected with the inflammatory process in the neighborhood, showed no bacteria in two cases. This result is surprising in view of the enormous number of bacteria always present in the large intestine. Of three cases of peritonitis diffusa, secondary to appendicitis or peri-appendicitis, the bacillus coli communis was found in two, the bacillus pyocyaneus in one, and one case was sterile. In this group of peritonitis diffusa are also three cases which had their origin in the gall-bladder, one being secondary to a choledochotomy. In two of the cases the bacillus coli communis was found, and in the third the staphylococcus albus.

In this connection it may be mentioned, that of three cases of gall-stones, the bile contained staphylococcus albus in one case, bacillus coli communis in one case, and the remaining case was sterile.

Of six cases of peritonitis from various causes, in two bacillus coli communis, in two streptococcus, in one bacillus pyocyaneus were observed. In a single case no bacteria were present. Four cases of intestinal obstruction formed another group of cases, in three of which there was a fibrinous exudation in the peritoneum. Of the four cases but one yielded an organism of any significance, namely, the staphylococcus albus. Two were apparently sterile.

The last group of cases are those in which the fluid of hernial sacs was examined for bacteria. Of seventeen cases all were sterile except two, and these positive cases were from four of beginning or advanced gangrenes of the gut. The absence of bacteria in the other two cases of gangrene, where the conditions for their migration through the wall of the gut were apparently favorable, is surprising. On the other hand, in the sac fluid of two out of three epiploic hernias, where bacteria from the intestine were scarcely to be expected, bacteria could be demonstrated. In two hernial hydroceles the fluid was sterile. These results are of interest as showing that we are as yet ignorant of all the causes which determine the migration of bacteria through the intestinal wall. It is also interesting to note that the examination of the contents of a hernial loop of the small intestine accidentally opened at operation showed few bacteria. This is another proof of the relatively small number of organisms in the small intestine as compared with those in the larger gut.

In addition to the foregoing cases, the authors have included in their list of examinations a number of other cases more or less germane to the subject of peritonitis, but which have no special interest. Among these, however, should be mentioned a case of sub-peritoneal abscess, and a case designated as empyema of a hernial sac, in both of which tuberculosis originating in the vertebræ has not been sufficiently excluded. The latter case especially serves to emphasize how desirable it is for the bacteriologist who works with pathological processes to have some knowledge of pathology.

The technique employed in the work is, on the whole, satisfactory. The study of the biology of the different bacteria is perhaps, in general, as thorough as is necessary. A feature of their investigation, which is of especial interest from a bacteriological point of view, is the study of thirty representatives of the bacillus coli communis with reference to their various cultural peculiarities, number of locomotor organs and other characteristics.

The results would seem to show that scarcely any two of them are exactly alike. The differences, however, in many cases, are only such as one would encounter in studying parallel cultures of almost any organism, and we do not think that the writers are justified in considering many of such differences as constant. It is well known that different varieties of the bacterium coli exist, but the division of these thirty representatives of that group into as many as twenty varieties does not seem warranted from the observations. Of the thirty, two at least are clearly not to be classed within this group of the bacterium coli, as would appear from a consideration of their cultural peculiarities as given by the writers. In several cases bacilli somewhat resembling the Klebs-Löffler organism have been observed. To these, however, no pathogenic significance is ascribed. We cannot agree with the writers that this is probably the pseudo-diphtheria bacillus of Löffler. The cultural peculiarities of that organism are too little known for it to be identified, and our own experience has seemed to show that there may be nearly as many pseudo-diphtheria bacilli as there are observers.

In addition to the results of their own experimental work, the speculative and historical aspects of various questions connected with the subject of peritonitis have been well considered by these investigators. As to prognosis, they state that no conclusion can be drawn from the species of bacteria present. In those cases, however, where no bacteria are to be demonstrated, it would seem that the result is, in general, more favorable than in those where bacterial forms are present.

Therapy also receives due attention. Especially valuable and noteworthy features of this contribution are thirty-two excellent reproductions of microphotographs of some of the bacteria observed.

"Man is a part of collective nature; his development proceeds not by leaps and bounds, but slowly out of past and present." — *Billroth's Autobiography*.

MEDICAL NOTES.

CHICAGO SMALL-POX STATISTICS. — During the month of January there was 128 cases of small-pox in Chicago, 29 of which were fatal, some before they could be removed to the hospital. There was seven cases of hemorrhagic variola, none of the patients having ever been vaccinated. There were many confluent cases, all in unvaccinated persons. A few of the fatal cases had been vaccinated in infancy, but never re-vaccinated.

A HOSPITAL FOR TUBERCULOSIS IN VIENNA. — The Emperor of Austria has made the anniversary of the death of the late Crown Prince Rudolph the occasion of giving a sum of 10,000 gulden towards the establishment of a home for tuberculous patients in Vienna.

THE ROYAL COMMISSION ON VACCINATION. — In an editorial upon the first volume of the long-expected report of the Royal Vaccination Commission, the *Lancet* says: "The evidence published in the volume shows that the difficulty that really has to be met is the readiness with which well-intentioned people can be misled. Perhaps one thought impresses the reader more than any other in studying the volume which has been issued. If one tithe of the pains had been taken to make known the risks of small-pox and the value of vaccination that have been expended on endeavors to prejudice the public against vaccination, it is not probable that the appointment of a commission of inquiry would ever have been deemed necessary."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, March 14, 1894, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 30, scarlet fever 36, measles 12, typhoid fever 5, small-pox 7 (no deaths). Two cases of small-pox have been reported to the State Board of Health from places outside of Boston; one from Waltham and one from Lynn (which is the first case in that city since 1873).

A WARNING TO BOSTON PHYSICIANS. — During the past week a sneak-thief has been plying his trade among physicians' houses, if given an opportunity to be left alone in the reception-room. He is a man about forty-five years old.

NOTIFICATION OF CHICKEN-POX IN BOSTON. — The Board of Health of Boston has given notice that in addition to Asiatic cholera, small-pox, scarlet fever, typhus fever, diphtheria, measles, typhoid fever, yellow fever and membranous croup, chicken-pox will hereafter be regarded as a disease within the meaning of Section 79, Chapter 80, of the Public Statutes, and that physicians will be expected to report all cases coming under their notice within the city.

A CENTENARIAN. — Mrs. Abigail Hobart, Nashua, N. H., passed her hundredth birthday last week, and with the exception of slight deafness is in possession

of all her faculties. She has had nine children, five of whom are living, with sixteen grandchildren and twenty-five great-grandchildren.

DEATH AT NEARLY ONE HUNDRED AND ONE. — Mrs. Sally Sawyer Case, who died in Wellesley Hills, Mass., last week, was one hundred years and ten months old. She was present at the funeral services of George Washington.

Miscellany.

AMERICAN GOUT.

LITHÆMIA is so preëminently the form in which gout shows itself in this country, that Da Costa has characterized it as "American Gout." As he has, by his former contributions to the subject, done very much towards giving us clearer views upon the pathology and therapeutics of this hydra-headed morbid state, a brief abstract of an unpublished address which he recently delivered, by request, before the students at the University of Pennsylvania, will prove especially interesting at this time.

By the term lithæmia is understood the morbid condition closely allied to gout, in which lithic or uric acid and other waste products, accumulate in the blood, and cause certain toxic effects, as well as interfere with normal metabolism. Symptoms like those of lithæmia have been found where the urine shows neither uric acid nor urates in excess, nor oxalates. They might be accounted for, perhaps, by the presence of waste products in the urine, such as acetones and peptones, though as yet no accurate chemical researches have been made on this point. It is convenient to retain the term lithæmia as broadly covering the state of the system associated with waste products, even though not specifically uric acid until we find a better name for the whole malady. The title "uricæmia," or even "uric-acidæmia," which has been suggested as a synonym for the older term, is not an improvement, since it implies that the symptoms are due entirely to excess of uric acid, which is taking quite too limited a view of its pathology. In fact, after referring to the theories of Murchison, Roberts, Haig and others with regard to the pathology of the lithæmic or gouty diathesis, Professor Da Costa declared that we must return to neuro-humoral views like those of Sydenham, which are more in consonance with the clinical phenomena than any of those recently proposed. The suggestion of Roberts that a less soluble form of uric acid salts is formed in gouty states (that is, bi-urates instead of normal quadrurates) is highly plausible, and may well account for the tendency to uric acid deposits, which, however, are very much less liable to be encountered in lithæmia than in typical gout. The urine of lithæmic patients, moreover, does not present exactly the same characters which it does in typical gout. It is, as a rule, dense, high-colored, and of higher specific gravity than normal urine. After over-indulgence at the table, the urine may deposit lithates and oxalates, and become darker in color and of higher specific gravity. It may become less abundant than normal, and, by concentration, cause albumin and even casts to appear for a time. This does not, however, indicate the presence of the well-known form of gouty, or contracted, kidney; on the contrary, the kidney is re-

markedly free from inflammation in lithæmia, and both albumin and casts rapidly disappear under appropriate treatment. The heart may be irregular and palpitation be complained of. It is apt to have a weak or muffled first sound; and this is followed by an accentuated, valvular second sound, due to increased arterial tension, which is also indicated by the sphygmograph. In lithæmia, however, cardiac degeneration and valvular disease, such as is common in gout, are remarkably rare, and cannot be said to belong to the clinical history.

The nervous and cerebral symptoms of lithæmia commonly found, are gloom, depression of spirits, irritability of temper, restlessness at night, drowsiness during the day, with disinclination to intellectual effort, jerking of muscles, myalgia, pains in tendons and neuralgia. There is also indisposition to muscular exercise, and the patient is quickly tired; flying pains may appear in various portions of the body, or actual cramps occur. Dyspeptic symptoms are common, though not constant, and there is a tendency to excess of acid in the stomach. Functional derangements of the liver are of frequent occurrence. Vertigo and migraine are prominent symptoms; and the vertigo, like that of stomach disorder, usually appears early in the day; while to increase of acid in the system the attacks of migraine may be ascribed; and the lecturer stated that, for prompt relief of the latter symptom, nothing could excel the effects of administration of hydrochloric acid. This, however, might be like applying ice-water to a gouty inflamed joint, which would promptly relieve the pain, but was attended by some risk of further injury to the patient.

The most prominent causes of lithæmia and gout are excessive eating and drinking, the body is burdened by an undue amount of nitrogen and carbo-hydrates, which the excretory organs cannot remove as fast as supplied, and waste material accumulates in the blood. This is less apt to occur, when active open-air exercise is kept up, than when the life is sedentary or inactive and oxidation is imperfect. The gastronomic achievements of the Emperor Charles V, as detailed by Roger Ascham, were quoted; and the gloom, depression of spirits and increasing melancholy, which finally led to his abdication and retirement to a monastery, were shown to be directly due to lithæmia and gout from excessive eating. Here, gluttony and consequent disease had an important influence upon history. If the emperor had not been lithæmic and gouty, he would not have been so gloomy and melancholic, and he would not have retired to a monastery; if he had not thus retired the Netherlands would not have been given up, and there would have been no Armada. And so great results may be traced to a monarch's self-indulgence.

Lithæmia may be inherited as well as acquired. It may be manifested early in life, and among adults is as frequent among women as men. Exceptionally the symptoms become those of ordinary gout, but joint inflammation does not, as a rule, occur, though there may be some painless enlargement of a distal joint of the little fingers of slow development, possibly several joints may be affected, or the finger-ends may become clubbed.

In the treatment, diet occupies the first place. In many cases restricting the diet to vegetables, especially the green vegetables, will be sufficient to dissipate all the symptoms. In most cases, it will not be advisable

or necessary to adhere strictly to a vegetable diet, and a moderate allowance of meat, if exercise be taken, is permissible, especially the white meat of poultry and fish, may be indulged in without harm. Fats are to be restricted in amount, and carbo-hydrates are to be excluded as much as possible, allowing patients to take only a small quantity of stale bread or biscuit. Most lithæmics declare that sugar does them harm. It is advisable to use especial caution against all articles which the patient finds by experience readily undergo fermentation in the stomach, as the acid aggravates the condition. The drink of the lithæmic should be water only, and enough water should be drunk to keep the kidneys flushed. All forms of alcoholic drinks are bad; but in elderly subjects, accustomed to their use, a very moderate quantity of old whiskey, or of a good claret, may be allowed with the meals. Champagne is particularly bad because it is generally acid in reaction, besides containing much sugar. The importance of fresh-air exercise has been already insisted upon, as the means of increasing metabolism and oxidizing waste. The skin should be kept in good condition, and the sweat-glands rather active. Woollen clothing is advantageous.

In conclusion, the medical treatment may be summed up in a few words. Laxatives, especially salines, are highly useful. Mineral waters are important adjuncts, these waters being better diuretics for these cases than drugs, which irritate or increase still further the blood-tension in the kidneys. To neutralize waste matters in the blood, carbonate of lithia (gr. ii) in capsules, with extract of *nux vomica* (gr. $\frac{1}{2}$), given several times a day, had been found very efficient, the *nux* acting as a general tonic, as well as affecting the heart. Piperazin is still under trial; it has been found of some service in lithæmic conditions.

As regards prognosis, a very favorable view can be taken. Living in accordance with the regimen above-indicated, reducing the quantity of the food to the actual demands of the system so that the in-come shall not be greater than the out-go, restricting the nitrogenized food, carbo-hydrates and fats; drinking only water, avoiding alcohol, and taking daily out-door exercise — this is the road to health for lithæmic sufferers, by pursuing which they will escape their threatened ills, and may in time feel themselves entirely cured of their malady.

THE INTERNATIONAL SANITARY CONFERENCE.

THE result of the International Sanitary Conference thus far has been to make more evident than ever before the difficulties attending any satisfactory control of the out-put of cholera from Mecca at the time of the pilgrimages. The committee on this subject has recommended that a system of medical inspection of pilgrims landing at ports of the Persian Gulf be established; but how it is to be organized, or in what way it is to be controlled, was not mentioned. The chief attention has been directed to the sea routes, although the greatest danger has in most years been from the land routes, over which there has been little or no control thus far.

The French and English delegates have differed a good deal over the conditions of port quarantine, the position of the British representatives, that to stop healthy passengers and a healthy ship does not prevent

but actually creates danger, being strengthened by Dr. Arnaud's description of the quarantine station at the island of Camaran in the Red Sea, where the accommodation is so bad that the disease is spread to passengers and crews detained there. "It is simply a dépôt of cholera, and there have been more epidemics since the opening of this quarantine station than there were previously." Great distrust is felt as to the intention or willingness of Turkey to carry out any agreement and as to the ability of the Persian Government to do so.

The inquiry of one of the United States delegates whether the Conference could not establish rules by which emigrants could be watched, examined, or controlled in such a manner as should prevent them from carrying over to the United States the germs of cholera, small-pox, and kindred diseases, opened up a wide field for discussion. He said, very fairly, that it was all very well to impose medical inspection on Mahomedan pilgrims embarking for Mecca, but why not take similar precautions with respect to emigrants embarking for America? The action of the Conference on this proposition will be watched with interest.

Socially the Conference has been an unprecedented success. The delegates have been entertained at dinners, balls and fêtes by public and private persons, with untiring hospitality.

Correspondence.

THE DIAGNOSIS OF SMALL-POX.

BOSTON, March 13, 1894.

MR. EDITOR:—The rare occurrence of small-pox in Massachusetts during the past twenty years (and since the great epidemic of 1872-73) makes it more than probable that scarcely one in ten of the physicians now in active practice has ever seen a case of this disease. When cases occur in the practice of young physicians, it not unfrequently happens that an error in diagnosis is made, especially during the first week of illness and when the disease is of a mild type. In consequence of such mistaken diagnosis, undue exposure has occasionally taken place, and the health of the community has suffered.

The writer has known several such instances during the past six months, and would therefore respectfully suggest to all young practitioners who have not had a considerable experience with small-pox, that they should in every doubtful case, request a consultation with some older practitioner who has had opportunity to see cases of this character. Such a course might not only prove advantageous to the young practitioner, but also to the community at large.

Respectfully yours, SENEX.

ARRANGEMENTS FOR ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

BOSTON, March 10, 1894.

MR. EDITOR:—Elaborate arrangements are being made in San Francisco for the reception and entertainment of the American Medical Association at its annual meeting in June. Special trains will run from Chicago, leaving on May 28th. It is expected that round-trip tickets will be furnished at the price of a single fare, with choice of returning by other routes. If a sufficient number attend from New England, special cars will be furnished from Boston. Members may be accompanied by friends.

Further information may be obtained by addressing,
HENRY O. MARCY, M.D.,
180 Commonwealth Avenue, Boston.

METEOROLOGICAL RECORD.

For the week ending March 3, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,303; under five years of age 849; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 332, acute lung diseases 469, consumption 258, diphtheria and croup 137, measles 31, scarlet fever 34, diarrhoeal diseases 27, whooping-cough 20, small-pox 18, cerebro-spinal meningitis 13, typhoid fever 18, erysipelas 11, malarial fever 3, puerperal fever 1.

From diarrhoeal diseases New York 10, Cleveland 1, Milwaukee 3, Washington and Fall River 2 each, Brooklyn, Boston, Springfield, Somerville, Salem and Fitchburg 1 each. From whooping-cough New York 7, Brooklyn 4, Cleveland and Nashville 3 each, Washington and Cincinnati 2 each, Boston 1. From small-pox Brooklyn 8, New York 6, Boston 4. From cerebro-spinal meningitis New York 7, Brooklyn and Lynn 4 each, Boston, Worcester and Marlborough 1 each. From typhoid fever New York 5,

Brooklyn and Lowell 4 each, Boston 3, Cleveland 2. From erysipelas Brooklyn 4, New York 3, Boston 2, Cleveland and Taunton 1 each.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 3, 1894, TO MARCH 9, 1894.

Leave of absence for one month is hereby granted CAPTAIN R. B. BALL, assistant surgeon, U. S. A., Fort Monroe, Va.

CAPTAIN R. W. JOHNSON, assistant surgeon, U. S. A., will proceed to Fort Monroe, Va., for temporary duty, during the absence on leave of CAPTAIN R. B. BALL, assistant surgeon. Upon the return of the latter from leave, Captain Johnson will return to his station, Washington Barracks, D. C.

FIRST-LIEUT. CHARLES WILLCOX, assistant surgeon, U. S. A., is relieved from temporary duty at Boise Barracks, Idaho, and ordered to return to his proper station, Presidio of San Francisco, Cal. Par. 7, S. O. 54, Hdqrs. of the Army, A. G. O., March 5, 1894.

Leave of absence for one month is granted MAJOR TIMOTHY E. WILLCOX, surgeon, U. S. A.

The leave of absence granted MAJOR JOHN D. HALL, surgeon, U. S. A., is extended one month.

Leave of absence for four months, to take effect on or about August 10, 1894, is granted CAPTAIN HENRY I. RAYMOND, assistant surgeon.

MAJOR JOHN VAN R. HOFF, surgeon, U. S. A., is hereby assigned to the charge of the office and duties of the medical director, Hdqrs. Department of the East, during the temporary absence of COLONEL JOSEPH R. SMITH, assistant surgeon-general, medical director of the Department.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 10, 1894.

F. W. OLCOTT, passed assistant surgeon, from Naval Hospital, New York, and to the "Richmond."

S. S. WHITE, passed assistant surgeon, from the "Richmond" and to the Naval Academy.

L. W. CURTIS, passed assistant surgeon, from the Naval Academy, Annapolis, and wait orders.

G. T. LUMSDEN, passed assistant surgeon, from the "Kearsarge" and wait orders.

W. H. JONES, medical inspector, ordered before the Retiring Board.

C. E. RIGGS, assistant surgeon, from Naval Hospital, Mare Island, Cal., and to Naval Laboratory and Department of Instruction, New York.

D. N. BERTOLETTE, surgeon, and J. M. MOORE, assistant surgeon, ordered to the "Atlanta."

J. E. PAGE, assistant surgeon, ordered to examination preliminary to promotion.

HARVARD MEDICAL SCHOOL. EVENING LECTURES.

The next lecture will be given on Wednesday evening, March 21st, at 8 o'clock, by Dr. J. J. Putnam. Subject, "The Present Status of the Therapeutics of Nervous Diseases." Physicians are cordially invited.

AMERICAN SURGICAL ASSOCIATION.

The annual meeting of the American Surgical Association will be held in the lecture-room of the Medical Department of the Columbia College, Washington, D. C., May 29, 30, 31 and June 1, 1894. The special subjects for discussion so far arranged are:

I. "The Surgical Treatment of Empyema," by John Ashhurst, Jr., M.D. Discussion opened by Drs. N. P. Dandridge, C. B. Nancrede, T. F. Prewitt and DeF. Willard.

II. "Methods of Teaching Surgery," by J. S. Billings, M.D. Discussion opened by Drs. J. C. Warren, N. Senn, W. W. Keen, E. M. Moore, W. T. Briggs and Hunter McGuire.

III. "The Surgery of the Kidney," by L. M. Tiffany, M.D. Discussion by Drs. M. H. Richardson, H. H. Mudd, C. H. Mastin and Ford Thompson.

IV. "Methods of Controlling Hemorrhage in Amputation at the Shoulder," by W. W. Keen, M.D. Discussion by Drs. Roswell Park, C. B. Porter and J. William White.

Fellows who desire to present volunteer papers are requested to send the titles of the papers to the address of the Business Committee, 1429 Walnut Street, Philadelphia, not later than April 18, 1894.

J. R. WEIST, M.D., Secretary.

AMERICAN MEDICAL ASSOCIATION.

SAN FRANCISCO MEETING, JUNE 5-8, 1894.

The Committee of Arrangements has secured Odd Fellows' Hall Building, Corner of Market and Seventh Streets, for the meeting June 5, 1894. Assembly Hall will be used for the general meeting, the twelve smaller halls for Section work. The engagement carries three of these rooms on Monday for accommodation of associate organizations, as that of the Editors, Colleges, etc.

Headquarters for the Association have been located at the Palace Hotel, corner of Market and Montgomery Streets, only four blocks from the place of meeting.

Post-Office Section K is located in the Palace Hotel, on the office floor, adjacent to the registration room, where members can receive all mail matter by having it so addressed.

R. H. PLUMMER, Chairman.

SECTION ON SURGERY AND ANATOMY.

It is proposed to devote a portion of the time of this Section to the systematic consideration of a few selected subjects, upon which papers, each not occupying more than ten minutes will be read. It is hoped that speakers discussing these papers will confine their remarks to brief addresses of five minutes' length.

The topics and papers to be so presented are as follows:

(1) Malignant Growths; (2) Tubercular Disease of Joints; (3) Hernia; (4) Hemorrhoids, Fistule and Fissure; (5) Fractures; (6) Obstruction to Urination in the Male.

Members who have specimens or patients to exhibit bearing on these topics or who wish to make remarks in the discussion of them are cordially invited to be present during the meetings of the Section. The titles of other papers to be presented to the Section will be published when the programme of the meeting of the Association is issued by the Committee of Arrangements.

JOHN B. ROBERTS, Chairman,
1627 Walnut Street, Philadelphia.

LLOYD W. MCRAE, M.D., Secretary, Atlanta, Ga.

RECENT DEATHS.

FRANCIS FLINT FORSAITH, M.D., M.M.S.S., formerly of Weymouth, Mass., died in Providence, R. I., March 10, 1894, aged sixty-nine years.

DR. ALBERT LUCKE, Professor of Surgery in the University of Strassburg and the colleague of Billroth in editing the *Deutsche Chirurgie*, died February 28th.

DR. DON VINCENT A. GARCIA, President of the Medical and Natural Science Society of Bolivar, Columbia, died recently.

BOOKS AND PAMPHLETS RECEIVED.

The Young Man in Business. By Edward W. Bok. Philadelphia. 1894.

The Forms of Peritonitis, Their Relation to Appendicitis and the Etiology of Each. By Roswell Park, A.M., M.D. Reprint.

A Critical Review of the Seventh Decennial Revision of the Pharmacopoeia of the United States of America. By George M. Beringer, A.M., Ph.G. Reprint. 1894.

A Practical Treatise on the Diseases of the Hair and Scalp. By George Thomas Jackson, M.D. New, revised and enlarged edition. New York: E. B. Treat. 1894.

A Speech on the Principles of Finance. By Victoria C. Woodhull, delivered at Cooper Institute, New York City, Thursday, August 3, 1871, and throughout the United States of America. London. 1894.

The Strike at Shane's. Goldmine Series No. 2, Sequel to Black Beauty. A Prize Story of Indiana. Written for, and revised, copyrighted and published by The American Human Education Society. Boston, 1893.

The Physician's Wife and the Things that Pertain to Her Life. By Ellen M. Firebaugh. Illustrated with forty-four photo-engravings of sketches from life. Philadelphia: The F. A. Davis Co. London: F. J. Reisman. 1894.

Atlas of Clinical Medicine. By Byron Bramwell, M.D., F.R.C.P., Edin., F.R.S., Edin., Assistant Physician to the Edinburgh Royal Infirmary, etc. Vol. II, Part III. Edinburgh: Printed by T. & A. Constable at the University Press. 1893.

Supplement to the Reference Handbook of the Medical Sciences. By various writers. Illustrated by chromolithographs and fine wood-engravings. Edited by Albert H. Buck, M.D., New York City. Volume IX. New York: William Wood & Co. 1894.

A Treatise on Headache and Neuralgia, including Spinal Irritation and a Disquisition on Normal and Morbid Sleep. By J. Leonard Coming, M.A., M.D. With an appendix. Eye-strain, a Cause of Headache. By David Webster, M.D. Illustrated. Third edition. New York: E. B. Treat. 1894.

Original Articles.

THE DIAGNOSTIC AND PROGNOSTIC IMPORTANCE OF LEUCOCYTOSIS.¹

BY RICHARD C. CABOT, M.D.,

Medical Intern, Massachusetts General Hospital.

THE material for this paper consists largely of blood counts, 332 in all, which I have made at the Massachusetts General Hospital within the last year; and for all of it I am indebted to the kindness of the visiting physicians and surgeons of the hospital, who have given me the freest access to their cases at all times. I am under special obligations to Dr. F. C. Shattuck and Dr. R. H. Fitz.

It is important to know exactly what leucocytosis is before we attempt to estimate its diagnostic or prognostic value. It is a very difficult idea to define. Not one of the authors whom I have consulted have seemed to me to give a satisfactory definition, that is, one which sufficiently distinguishes it from leucæmia. Von Jaksch,² for instance, distinguishes it from leucæmia by its transitoriness, but it may last as long as leucæmia. Virchow defined it as an increase in the white cells of the blood due to a stimulation of the lymph glands, but in typhoid the increased glandular activity causes no leucocytosis.

Eichhorst, Jürgensen, Seifert, Müller, Strümpell, Vierordt and Pée³ in their text-books give it to be understood that leucocytosis is transitory, symptomatic, and less in degree than leucæmia; but counts as large as those in leucæmia have repeatedly occurred in cases where none of the characteristic lesions of leucæmia were present, especially in connection with malignant disease and the anæmiæ of children (Von Jaksch).

Very probably many of the reported cases of acute leucæmia where nothing was found at autopsy, were simply leucocytosis. The reported developments of pseudo-leucæmia into leucæmia were probably all leucocytosis. At any rate, I have not been able to come across a single such case where the crucial test of the differential count was applied. The mere increase in the white was held to constitute leucæmia.

On the whole, the best definition that I have been able to arrive at is this: Leucocytosis is the presence in the blood of an increased number of white cells of the same varieties morphologically as those in normal blood, a plurality and generally an overwhelming plurality being polynuclear.

In leucæmia many of the varieties of white cells present have never yet been found in normal blood, although every one of them has now been found in diseases other than leucæmia.

In leucæmia the polynuclear cells are never increased, and are generally in minority. In leucocytosis the polynuclear cells are generally much increased, and are never in a minority.

But we cannot say, as Friedländer⁴ does in his short and pungent definition, that: "Leucocytosis is an increase in the polynuclear or other varieties of white cells present in normal blood"; for in pure lymphatic leucæmia there are no varieties other than those found in normal blood, the diagnosis being made

on the overwhelming majority of lymphocytes, or small mononuclear white cells, taken in connection with the other physical signs.

Practically, 90 out of 100 leucocytoses are perfectly easily distinguishable from leucæmia by their enormous percentage of the polynuclear varieties, 90 to 98 per cent. being the rule.

We cannot, then, make the distinction from leucæmia simply by the count. As an example of this, let me cite a case occurring in the wards of Dr. Maurice H. Richardson last summer, in which a mistaken diagnosis was made for lack of a differential count.

A. M., single, age twenty-one, entered with a diagnosis of malignant tumor. She was so pale that an examination of the blood was made. This showed an overwhelming number of white cells, 1 to 89 red; and taking this fact in conjunction with the position and nature of the tumor, a diagnosis of leucæmia was made. The tumor was in the region of the spleen, projecting below the left ribs, and it was thought that a notch was felt upon its upper surface. The patient was transferred to a medical ward; and here, after considerable delay, a triple stain and differential count of the blood was made, which at once showed that it was not leucæmia, for 95 per cent. of all the white cells present were of the polynuclear type. Not long after this, the tumor began to assume a position near the median line, and a zone of resonance appeared between the left ribs and the tumor. During her stay on the medical side she had several well-marked chills. She was transferred to the surgical wards again, and the tumor was tapped in several directions, nothing but a little fecal matter being obtained.

She failed rapidly, decided to go home, and was lost sight of; but her death was reported in the papers within a few weeks. No autopsy. This was probably a case of large malignant new growth and the count, 1 to 89, was not higher than has been repeatedly found in large abdominal tumors. I have collected eight cases of malignant growths from literature in which the count was 1 to 50 or greater.

On the other hand, we may have leucæmia with no increase in the number of white cells. A few months ago Dr. Hubbard, of Taunton, sent me some blood-slides from a case of leucæmia, Mrs. S., which I had seen and counted in the hospital a year before in the service of Dr. Shattuck and which is now under Dr. Hubbard's care in Taunton. *They showed no increase at all in the white cells*; but on making a differential count, a large proportion of the white cells present were found to be myelocytes, so large a proportion as could only occur in leucæmia. The patient has still all the other signs and symptoms of leucæmia. In leucocytosis then, as distinguished from leucæmia, we have only those varieties of white cells present which are found in normal blood.

We have said that leucocytosis is an increase in the white cells over the normal number. This normal number has been somewhat disputed; but the majority of careful observers in late years agree in placing it at or near 7,500. Any variation, of more than 1,500 above or below this number is to be considered abnormal.

Now, leucocytosis is found in a considerable number of physiological conditions. This must be carefully borne in mind if we are to rightly interpret its significance in disease.

Digestion.—We have in the first place leucocytosis

¹ Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, January 17, 1894.

² Von Jaksch: *Klinische Diagnostik*, 1889.

³ Pée: *Untersuchungen über Leukocyten*; *Inaug. Dissert.*, Berlin, 1890.

⁴ Friedländer: *Microscopische Technik*.

during digestion. This has been doubted by many authors; but the weight of authority is in favor of it, at any rate under certain conditions. Two and one-half hours after a meal rich in proteids the blood of most normal persons shows an increase of white cells varying from 1,000 to 7,000 above the normal.

Rieder,⁶ who has made a most thorough investigation of the subject, says that in adults the digestion leucocytosis rarely if ever goes above 13,000. Von Jaksch states that it may be so great as to cause a ratio of 1 white to 100 red, but he gives no cases in support of his assertion; nor does Klein,⁷ who asserts that the white cells may reach 20,000 simply from digestion.

In children it may be a good deal higher, but never, I think, so high as the estimate of von Jaksch. My own investigations of this matter agree entirely with those of Rieder. In 21 cases, on various diets, I have never seen it rise above 13,000. In 13 of these it was absent altogether.

Pregnancy.—Next may be mentioned the leucocytosis of pregnancy and the puerperal state, which occurs in about two-thirds of all cases; it is generally moderate, not over 14,000. The leucocytosis of pregnancy might be of value in excluding those cases of phantom tumor simulating pregnancy. This has not been done as far as I know.

Children.—New-born children have a very considerable leucocytosis; which falls gradually, until at the sixth year the count becomes normal. At no time during the first year is 12,000 abnormal. Besides these physiological conditions, we must bear in mind hæmorrhage, which, if large, may cause considerable increase soon after the loss of blood; also the leucocytosis occurring just before death, so-called leucocytosis of agony. If these causes are excluded, any leucocytosis may be called pathological.

Typhoid.—Taking up now the diseases in which the count of leucocytes is important, I shall begin with typhoid. Most febrile diseases are accompanied by leucocytosis; and Strümpell, in the edition before the last, of his "Text-Book of Medicine," makes the mistake of saying that leucocytosis is present in typhoid. In this he only follows the lead of such authorities as Virchow, Vierordt and others, who, judging apparently from *a priori* considerations, have stated that in all diseases accompanied by increased activity of the lymph glands, increase of white cells should be found. As a matter of fact, however, the overwhelming majority of observers, and almost all the facts, are on the other side. As mentioned in Osler's text-book, Thayer has counted nearly 150 cases, not reported in detail as far as I know, in which no increase was found. Rieder, v. Limbeck,⁸ Pick⁹ and others have come to similar conclusions. Leucocytosis occurring in typhoid points to some complication, such as thrombosis, pneumonia, abscess, etc. The diagnosis between relapse and some of these causes of temporary rise of temperature may, perhaps, be assisted by the blood-count. In a patient of Dr. Shattuck's, who had just recovered from a thrombosis during convalescence of typhoid, the temperature began to rise again. The question arose, whether this was due to the smouldering remains of the thrombosis (which, when active, had

caused both fever and leucocytosis), or whether the patient was having a relapse. The blood-count was normal; two days later rose-spots appeared, and the subsequent course of the case confirmed the diagnosis of relapse as indicated by the blood-count.

In the last few months I have counted 79 cases of typhoid fever. In only one was leucocytosis present, and that was in a child of four, where the normal number of white cells was so great that the count in this case, 1 to 300, may not be really leucocytosis at all. In 49 of my cases the number of white cells was less than the normal, and this agrees with most of the latest observations. Lack of time prevented my making more than one count in each case of typhoid.

Cold baths, as recently observed by Thayer, may produce a temporary increase. In two of my cases I was able to confirm this observation.

Now this fact, the absence of leucocytosis in typhoid, is a very important one in the diagnosis of that disease, for a large number of affections with which typhoid is likely to be confounded *do* show leucocytosis. Local suppurations, for instance, which are sometimes difficult to distinguish from typhoid fever, almost always produce leucocytosis. Purulent meningitis has shown in every case which I have been able to find in literature (only seven in all) a very marked leucocytosis. I have only one case to add to this.

Last September, a man entered the Massachusetts General Hospital with a diagnosis of typhoid fever. He had the typical "typhoidal" aspect. Low, muttering delirium, heavy coated tongue, temperature 104.2°, pulse 115, respiration 22. He could give no account of himself, and complained of nothing in particular. Physical examination was generally negative. No rose-spots were present, no spleen was felt, and there was no distention. The diazo reaction was present. In the absence of any other obvious diagnosis, the case was considered one of typhoid. The blood-count, however, showed 22,000 white cells. Next morning the patient's brother arrived, and stated that the patient had been suffering for years with middle-ear catarrh. There was no discharge from the ear; but Dr. Green found purulent otitis, with perforation in the left ear, and made a diagnosis of meningitis. The patient became unconscious within a few hours, and died two days later. No autopsy.

Ewing reports a number of cases in the *New York Medical Journal*, December 16, 1893, where the diagnosis was very difficult between pneumonia and typhoid until an examination of the blood cleared it up. No such difficulty has occurred in the cases I have seen, but, should it arise, the blood would undoubtedly decide in the great majority of cases.

Typhoid vs. Appendicitis.—A diagnosis between typhoid and appendicitis has presented considerable difficulty in several cases which I have seen at the hospital this year. As is well known, the pain of appendicitis may be very slight, and the tenderness no greater than is occasionally found in typhoid. The histories in a certain number of cases are not markedly different. In two such doubtful cases where I have found no leucocytosis, a diagnosis of typhoid has been confirmed by the subsequent course of the disease.

Three years ago, I saw in the hospital, in the service of Dr. Shattuck, a case in which the diagnosis between typhoid and some internal suppuration was for several weeks doubtful, until at last an abscess of the liver came to the surface and was opened. In

⁶ Rieder: Beiträge zur Kenntnis der Leukocytose, Leipzig, 1892.

⁷ Klein: Volkmann's Sammlung Klinische Vorträge, Dec. 1893.

⁸ Von Limbeck: Grundriss einer Klin. Path. des Blutes, Jena, 1892.

⁹ Pick: Klin. Beobachtungen über die Entzünd. Leukocytose Prag. Med. Wochenschrift, 1890, No. 24.

such a case as this I think the blood examination would have settled the difficulty at once.

Grippe.—Between grippe and typhoid the blood does not help us, for in neither are the white cells markedly changed. I have counted but five cases of uncomplicated grippe, but in none of these, and in but few of those which I have found in literature, has increase been present.

Between general sepsis and typhoid a blood-examination was of value in a case occurring this autumn in Dr. Shattuck's service. Patient presented symptoms and signs of acute polyarticular rheumatism with fever. The fever came down under salicylates, but soon rose again, and the man became wildly delirious. His delirium persisted after the salicylate was stopped. Several joints continued swollen and tender. The fever was very moderate, ranging between 99° and 101°. There were no rose-spots and no spleen. The question arose as to whether it was a case of sepsis with localization in the joints, or whether it was a case of typhoid supervening on an arthritis of some kind. The blood-count, which was repeated several times, showed always a perfectly normal blood except for a slight anemia. The subsequent course of the case, during which he remained for nearly three weeks more or less delirious, convinced Dr. Shattuck that it was a case of typhoid fever.

Tubercle.—As between typhoid and incipient pulmonary tuberculosis or tubercular meningitis, the blood does not give us any help. For in pulmonary tuberculosis all observers agree that leucocytosis is present only in advanced cases with high fever (that is, I suppose, in those where the infection is mixed) and in tubercular meningitis there is no leucocytosis, so far as observed. My own counts in tuberculosis in eleven cases have coincided with the results obtained by others. In two cases of galloping consumption and two cases of empyema with phthisis, leucocytosis has been present. In the other cases, consisting of two cases of tubercular peritonitis, two of early phthisis, two of tuberculosis of the kidney and one of general miliary tuberculosis, no increase has been present. I have only been able to find four cases of miliary tuberculosis in literature where counts have been made. In none of these was there any increase, so that in these cases of tuberculosis which would be likely to be confounded with typhoid the blood does not help us. The same is true of malaria, where a normal blood-count is found.

I stated before that the majority of cases of typhoid show by the second week leucopenia, or lack of white cells. Cases of debility with fever, and with or without gastro-intestinal symptoms, which are sometimes difficult to tell from typhoid, may, perhaps, be distinguished from it in some cases by their normal count. Two cases of acute gastro-intestinal catarrh with fever, which I counted with a view of finding out the cause of the fever, both showed a decided increase in white cells. This might be of use in a diagnosis of typhoid.

Pneumonia.—It has long been known that pneumonia shows a marked increase in white cells. I published the blood-counts of 48 cases last summer, in all but 5 of which leucocytosis was present.⁹ I dwelt then upon the prognostic significance of the absence of increase in the white cells, for all of the 5 which had no increase died. Since then I have counted 24 more, or 72 in all.

I will speak first of the diagnostic importance of blood in pneumonia. In the cases that I have seen it has helped mostly in distinguishing pneumonia from grippe, or rather in anticipating the complication of pneumonia in grippe. In three cases seen last month where no physical signs of pneumonia were present, where the history might do either for grippe or pneumonia, the high leucocyte count made me suspect pneumonia, and this was verified in each case by the appearance of signs of consolidation within thirty-six hours.

It is important before any treatment or any prognosis to make this distinction between grippe and pneumonia as early as we can, especially if we are in the habit of treating grippe with phenacetine.

Ewing, in the article mentioned above, says that he found a connection between the count and the amount of physical signs, and also between the count and the vigor of the systemic reaction. In my cases I have not been able to establish any such connection. High counts have been present in athenic and in fatal cases repeatedly; low counts in those with much lung substance involved. Of the 24 new cases since my last report on pneumonia, two have had no leucocytosis. One of these died. The other did not; but the course of the case was so interesting that I think it will be worth reporting in a little more detail.

The patient, L., was seen in Dr. Fitz's wards a few weeks ago, and was evidently a very mild case of pneumonia. Temperature and pulse were not high; there was no cyanosis, and but little lung involved. The man was perfectly sensible; and after the count, which showed a normal number of leucocytes, I felt as if the theory were certainly at fault in this case. The man was evidently going to get well. Within twelve hours the temperature rose to 105°; the pulse to 160, and became so weak as to be almost uncountable. The man became much cyanosed and wildly delirious. He seemed almost moribund, and remained in this condition for forty-eight hours. At the end of this time he began to improve a little. The count was repeated, and found to show a marked increase in the white. He ultimately recovered. Now here was a case where from ordinary appearances a good prognosis would have been given; but if we could have anticipated what his condition would be twenty-four hours afterwards, the prognosis would have been the very reverse. *The blood did anticipate it*; so that this case does not seem to me to be one which tends to upset the prognostic importance of the absence of leucocytosis in pneumonia. Of my 72 cases, 7 had no leucocytosis; 6 of these have died; and the other came so near it that if it had been foreseen what his condition would be, a very unfavorable prognosis would have been given. It is interesting here to see that when his condition began to improve, the leucocyte count rose.

Phthisis and Pneumonia.—Between pneumonia and phthisis in the early stages the blood-count might be of value, but it is not in this stage of phthisis that the difficulty of diagnosis would be likely to occur. Pleurisy with serous effusion shows, according to v. Limbeck and Pick, moderate leucocytosis in febrile stages, none in the quiescent afebrile stage. I have counted six cases, two in the febrile stage and four in the afebrile stage; and my results are entirely in accord with those of the writers above mentioned. Rieder thinks (on the evidence of a very small number of counts) that tubercular effusions give no increase in leucocytes, even when febrile.

⁹ Cabot: Boston Medical and Surgical Journal, August 3, 1893.

In three cases of empyema, I have found moderate leucocytosis, but not greater than that present in the febrile stages of serous effusions, so that no help is given by the blood-count, as between empyemas and serous effusions in the febrile stage.

Scarlet Fever and Measles.—Between these two diseases the blood is said by several authors to be of greater diagnostic importance, leucocytosis being present in scarlet fever and not in measles. I have had no personal experience in these diseases. According to Koczetkow, leucocytosis is present in scarlet fever in the incubation stage early as six days before the eruption.

In *Rheumatism* but few counts have been made. In the febrile stages the white cells are apparently increased. The same is true of erysipelas. In two cases I have found marked increase.

Diphtheria shows as high a count as any febrile disease. According to v. Limbeck the higher the count the worse the prognosis.

In *Follicular Tonsillitis* Halla has found moderate leucocytosis; and I have found the same in three cases, all febrile ones.

Experiments in the inoculation of animals with cultures of various pyogenic cocci show that those animals in which no leucocytosis is present generally die. This has been observed in a number of cases in the inoculation experiments at the Pasteur Institute last year.

Malignant Disease.—Leucocytosis occurs in a certain proportion of cases of malignant diseases. Just what that proportion is and what relation the count bears to the presence of the disease in one or another organ, or to the kind of disease, does not seem to me to have been settled as yet.

V. Limbeck found it most frequently in soft, growing tumors, and constantly in osteo sarcoma. Here the count may be of great importance in helping the diagnosis between malignant disease or some other form of joint affection. Tuberculosis, for instance, as before mentioned, does not cause an increase in the white cells; nor does chronic arthritis sicca, nor gonorrhoeal arthritis.

Gastric Cancer and Ulcer.—Schneider has, during the last year of two, maintained the thesis that the examination of the blood is of great importance in the diagnosis between cancer and ulcer of the stomach. He has found leucocytosis in all of 12 cases of cancer of the stomach and failed to find it in a number of ulcers. It is important here, however, to rule out all these cases of ulcer where profuse hæmorrhage has taken place, or where a long-standing chlorosis is present, for chlorosis and hæmorrhage both may cause leucocytosis. In cases of ulcer not dependent on these causes, it seems that the count might be of diagnostic value. I have counted only two cancers of the stomach, and there leucocytosis was present. I have counted no ulcers. In the diagnosis between anæmia secondary to malignant disease, and the simple primary or pernicious anæmia, the count is certainly of importance; for in these latter forms of anæmia, no considerable increase is often found, and although the absence of leucocytosis would not be of any great diagnostic importance, its presence might be. Moreover, Klein, the latest and most enthusiastic writer on the subject, states that in malignant disease, even where no leucocytosis is present, a differential count shows a marked increase in the percentage of polynuclear cells. In cancers of the uterus it has been found less often, and in cancer

of the gullet it apparently does not occur, the white cells being decreased.

I have counted 19 cases of malignant disease and found leucocytosis in 12. In my cases a leucocytosis was present wherever cachexia was present, without any particular reference that I can trace to the position or nature of the tumor. The 7 cases where no increase has been present have been mostly small tumors, and all in persons where no cachexia was present. Thus, in a small cancer of the lip, a sarcoma of the testis, and a sarcoma of the abdominal wall, there was no increase. In all of these cases the tumors were small, and there was no cachexia. In one case of cancerous growth filling the whole pelvis, and in another case of very large sarcoma, probably of both suprarenal capsules, both without cachexia, there was no increase. The last of these two cases became cachectic, and several months after the first count the leucocytosis rose proportionally. In one case of multiple sarcoma of the skin where the tumors were very small, although fairly numerous, there was a large increase; but here again the patient was markedly cachectic.

Appendicitis.—I have counted 24 cases of appendicitis, and have been specially interested in these counts, because leucocytosis if constant in appendicitis would be a diagnostic factor of some value. In every case except two where pus was found at operation, leucocytosis was present, the size of the count having, as far as I could judge, no relation to the amount of pus found. In three cases of appendicitis proved at operation to be catarrhal, no increase was present, as was the case in several others whose course made the diagnosis of catarrhal appendicitis probable, although this was not actually verified by operation. The count has seemed to me of real value in some cases where the diagnosis was difficult, between simple colic due to constipation (with or without gastro-intestinal symptoms) and true appendicitis. Two cases where symptoms and signs pointed decidedly towards appendicitis, but where no leucocytosis was present were relieved of all these symptoms within forty-eight hours, by clearing the bowels. The count may be of use, it seems to me, in deciding us whether an enema ought to be given. It is sometimes desirable to give an enema in cases simulating appendicitis to help clear up the diagnosis, but some physicians are afraid to do so for fear of causing a walled-off abscess to break into the general peritoneal cavity. In such cases, if no leucocytosis were present, we might go ahead with a clearer conscience.

Mr. B. entered the Massachusetts General Hospital September 20th, with a diagnosis of appendicitis. For twenty days he had been having pain and tenderness in the region of the appendix, pain being controlled by morphia. The bowels had been loose, he said. There was dullness and tenderness and a distinct tumor in the region of the appendix, with slight pyrexia. The blood-count showed only 8,000 leucocytes. He was given a compound cathartic pill, had a large movement of the bowels, and all symptoms and signs disappeared. V. Limbeck, Rieder, Pick and Koblauck²⁰ all state unconditionally that leucocytosis is present in general septic peritonitis with fever. But in three cases of general peritonitis, two of them with appendix present, no increase of white cells has been present. I do not know how to explain these cases. It is possible that they may be explained in the same way as the

²⁰ Koblauck: Inaugural Dissertation, Berlin, 1889.

absence of leucocytosis in some fatal cases of pneumonia. All these three cases of peritonitis died within twenty-four hours. It may be that the lack of leucocytes is a point in prognosis, pointing to a feeble systemic reaction. It is interesting also that in none of these three cases was there any pain, while in every one of those cases where I found leucocytosis, pain was a marked feature. This would suggest that pus under tension is more likely to cause leucocytosis than where free. The same thing is suggested by counts that I have made in felons and small abscesses in the Out-Patient Department. In three felons, one of which contained less than half a drachm of pus, I found well-marked leucocytosis. In a paronychia with great pain, but without pus, no increase was present.

Pus-Tube.—In 15 cases of pus-tube or pelvic abscess I have never once failed to find leucocytosis. This fact may serve to help in the diagnosis between pus-tube and pelvic abscess, on the one hand, and those pelvic pains with no anatomical basis, and other non-suppurative and non-malignant pelvic affections, such as extra-uterine pregnancy, pelvic hæmatoma, and small ovarian cyst, on the other. In two cases of extra-uterine pregnancy I have found a normal blood-count. I may mention here two interesting cases of severe inflammation under the scalp, following scalp wounds. In one of these I found normal blood-count; and at operation no pus was found, only boggy, water-soaked tissue. In the other I found leucocytosis, and plenty of pus appeared on making a cut.

Septic Hands, etc.—I have counted three septic hands and one septic foot, and always found leucocytosis. The same is true of three buboes and two small abscesses of the neck. One case of mumps showed normal count.

Osteomyelitis.—Two cases of osteomyelitis with deep seated suppuration (as proved by subsequent operation) showed marked leucocytosis, while one with similar symptoms, but normal blood-count, turned out to be rheumatism. Three cases of otitis media were counted. Two of them were purulent and had leucocytosis; one was serous and had none. In one case of housemaid's knee in which the general constitutional symptoms were more marked than usual, so that the presence of pus was thought of, I found large increase in leucocytes; and a few hours after pus was found at operation. Two joint cases, one of the elbow and one of the knee, where before operation the question of pus was seriously entertained, showed normal counts, and no pus was found in either. Besides the three cases of general peritonitis mentioned above, where the indication of the blood-count was wrong, there should be mentioned a large abscess, apparently originating in the liver, which burrowed forward and was evacuated in the epigastrium, and which showed a normal blood-count. I have no idea why the blood-count failed in this case.

Obstruction.—In three cases of intestinal obstruction, one of them so closely simulating appendicitis that it was sent in by a surgeon of the Massachusetts General Hospital with that diagnosis, no leucocytosis has been found.

Carbuncle.—Two cases of carbuncle showed, as was expected, marked leucocytosis.

Cystitis, etc.—Two cases of cystitis, and three cases of endometritis showed normal count, as did two cases of so-called urethral fever following operation on bladder.

Healing Wounds.—On the whole, the cases where the blood has seemed to me of greatest importance have been those where after the operation, the wound having been sewed up tight, the question has arisen whether pus was forming inside. I shall speak of these somewhat more in detail.

CASE I. Frank B. was a case of appendicitis operated on by Dr. Richardson at the end of an attack. A little pus was found, the appendix was excised, and the wound nearly closed, a small strand of gauze, however, being left in. Several days after the operation, there being at the time no external discharge, the temperature rose. The wound seemed perfectly clean. The man was very nervous about himself, and much stirred up at each dressing; and as the temperature never went higher than 101° , there seemed to be considerable doubt as to what the cause of the temperature was. The blood-count in this case showed 52,000 leucocytes; and on opening the wound a large amount of broken-down blood-clot was evacuated, and the temperature came down to normal.

CASE II. Mrs. S. was a case of pus-tube shelled out and sewed up tight. Ten days after the operation the temperature began to look a little like pus. Here again the patient was exceedingly nervous; and, as so often happens, the question was asked and re-asked, whether she was keeping up her own temperature by the state of her mind. The blood-count, however, showed marked leucocytosis, which led to a careful ether examination, revealing a fluctuant mass behind the uterus, from which pus was obtained by puncture.

CASE III. Mr. R. entered the Massachusetts General Hospital in December, under the service of Dr. Porter, with a compound fracture of the thigh. Some days after it had been put up, the temperature began to look like pus, the wound, however, remaining perfectly clean. I counted the blood, and found a marked leucocytosis. A more thorough exploration of the wound revealed a pocket of pus, the evacuation of which brought down the temperature. I was not sure in this case whether the absorption of the blood-clot, such as takes place, I suppose, after any compound fracture would be sufficient to cause leucocytosis. I therefore counted several cases in which there was fever and presumably blood-clot absorption, namely, a hæmothorax, a pelvic hæmatocele, two compound fractures and a crushed foot; in none of these was any leucocytosis present.

CASE IV. Mr. S. was operated on by Dr. Warren for traumatic epilepsy. Nothing special was found, and the wound was closed. Ten days after the operation the temperature rose to 104° , and the patient complained of severe headache and pain in the back. I counted the blood, and found no leucocytosis. Next day the temperature was down. The patient apparently had the grippe.

There is no time to report more cases in detail, but these last cases have seemed to me to be very suggestive and interesting.

CONCLUSIONS.

Only in typhoid and in pneumonia does the number of counts which I have made warrant any conclusion. The absence of leucocytosis in typhoid and its presence in pneumonia (except in the severest cases) seem to me fairly well established and of some diagnostic and prognostic importance.

The number of cases counted among the surgical af-

fections is too few to warrant any conclusions; but they are sufficient, it seems to me, to make it important that the subject of leucocytosis in surgical cases should be studied much more carefully, with a view to its practical diagnostic value. If a felon with half a drachm of pus in it will cause marked leucocytosis, it certainly seems as if the diagnosis of deep-seated suppurations of larger size might be helped out by blood-examinations, as apparently it was in some of the appendix and osteomyelitis cases I have quoted.

Into the interesting and possibly important subject of the diagnostic importance of qualitative changes in the varieties of white cells, which is being so eagerly pushed in Germany just now, I have not undertaken to enter. Its advocates say it is even more important than the quantitative variations dwelt on in this paper.

TECHNIQUE.

In most of the cases reported above I have used the Thoma-Zeiss counter with Hayem's or Gower's solution and a dilution of 1 to 200. So great a dilution is condemned by German writers, as affording too small a number of leucocytes for computation, and so increasing the chance of error. To avoid in part this difficulty, I measured the field of my microscope, using always the same lenses. It happens to measure almost exactly one-quarter of a square millimetre, so that four fields of my microscope are just equal to the whole four hundred ruled squares of the Thoma-Zeiss instrument. By taking four fields in each of the four directions away from the sides of the ruled space of the instrument, we have counted as many leucocytes as we should have done by taking four additional drops from the pipette and counting only the ruled space. As the lines extend out some distance beyond the squares on each side, we can use them as a guide to start us in the right direction; and by using a movable stage, we can be sure of not getting off the track and into fields already counted. After counting one field, the eye is fixed on a corpuscle at the side of the field most distant from the central ruled squares, and then by means of the moving stage the slide is moved until that corpuscle is on the inner edge of the field, that is, that nearest the ruled squares. By counting four fields in four directions, I had with the central ruled space twenty thousand squares as a basis of computation. In each count I did the whole process over with a second drop as well, making forty thousand squares in all. This gives us in most cases from fifty to one hundred leucocytes as a basis of computation, which makes the error considerably smaller.

I have used also the one-third per cent. acetic-acid solution, which makes the red corpuscles invisible, and can therefore be used with much less dilution than the other solution, 1 to 20 being that generally used abroad. I have used generally 1 to 50, and found the results obtained by counting the same blood first with Gower's solution (1 to 200) and then with the acetic acid to be so nearly the same that I have fallen back onto the 1 to 200 dilution, which has the advantage (besides that of needing less blood) that it does not deprive us of the count of red corpuscles, whereby we may check any mistake in our mixing by reference to the ratio of red to white. If the red are invisible (as with the acetic-acid method) we are deprived of this advantage.

MIKULICZ, of Breslau, is under consideration as the successor of Billroth at Vienna.

TWELVE CONSECUTIVE AND SUCCESSFUL OPERATIONS FOR APPENDICITIS.

BY JOHN W. KEEFE, M.D., PROVIDENCE, R. I.,

Visiting Surgeon to St. Joseph's Hospital, Surgeon to Out-Patients at the Rhode Island Hospital.

MORE has been written upon the etiology, pathology and treatment of appendicitis during the last five years than upon any other disease. Even the daily press has taken up the subject, and expatiated with more or less correctness upon the many phases of this so-called "fashionable disease." The operative treatment is, without doubt, the method of procedure in the large majority of cases. In Bull's collection of cases, treated without operation, there was a mortality of 47.67 per cent.; in Noyes's collection of 100 cases, treated by the Willard Parker operation, there was a mortality of 15 per cent.; while the mortality in the early operation, or during the first three days of the disease, is only 15 per cent. It has been shown that about 84 per cent. of those who die, do so within the first five days. I am fully convinced that the early operation by a skilful surgeon, will save the greatest number of lives. When the disease is of several days' duration, and the symptoms and signs continue, the Willard Parker operation is the operation of election. The mortality is about one per cent. in cases operated upon between the attacks in recurrent cases of appendicitis.

CASE I. J. W., male. Age nineteen years, telegraph-operator and switchman on the N. Y., P. and B. R. R.

May 4, 1891, while witnessing a base-ball game, felt a slight pain across the abdomen. The pain continuing, his mother administered a dose of castor oil, which produced a small movement.

May 5th. Remained in bed all day, and was attended by a homoeopathic physician, who prescribed some medicine to relieve pain.

May 6th. About 4 A. M. he had a very severe paroxysm of pain, which was almost unbearable. Tincture opii was given, and he experienced some relief. Nausea and vomiting. I saw him for the first time at 10 A. M.; his temperature was 103.5°, and pulse 120. He had pain over McBurney's point, and tympanitic percussion over right iliac region. Evening temperature 103.5°.

May 7th. Temperature 103°, pulse 120. Dulness on percussion, and sense of resistance in right iliac region. Rigidity of right abdominal muscles.

May 8th. No marked change in symptoms. Temperature 102.2°, pulse 110.

May 9th. Temperature, morning 100.6°; evening, 101.8°. Mass in right iliac region defined. Consultation with Dr. Noyes. Operation advised.

May 10th. Operation at 10.30 A. M. Present, Drs. Noyes, Mitchell and Collins. A vertical incision four inches long was made, two inches to the left of the anterior superior spinous process of the ileum, through the abdominal wall, which was not more than three-eighths of an inch in thickness, into a circumscribed intra-peritoneal abscess. About four ounces of very fetid pus was evacuated. A counter-opening was made in the loin, and a drainage-tube drawn through both openings. Coils of agglutinated intestine could be felt through the opening. The cavity was washed out with a 1 to 2,000 bichloride-of-mercury solution, and an antiseptic dressing applied. Four

silk sutures were used to partially close the anterior wound.

May 11th. Patient rallied well from the effects of the operation. Morning temperature 101°, evening, 102.2°. The wound was irrigated daily with a 1 to 2,000 bichloride-of-mercury solution, and an antiseptic dressing applied.

May 12th. Morning temperature 99.5°, evening temperature 99.8°.

May 13th. Free fecal discharge from wound. Morning temperature 98.8°, evening 99.5°.

May 14th. Two of the sutures were removed. Morning and evening temperature 98.8°, and pulse 96.

May 15th. Temperature and pulse normal. Only a slight discharge of pus. Two remaining sutures removed.

May 22d. Drainage-tube removed.

June 2d. Wounds entirely healed.

June 5th. Able to sit up.

June 6th. Four weeks from the day of operation ; went out of doors.

July 6th to 15th. Had an attack of cholera morbus.

August 31st. Ventral hernia, about the size of a walnut, near the centre of the anterior wound. Truss recommended.

December 6th. Hernia scarcely perceptible.

CASE II. F. E. P., male, age twenty-eight, baker. This man was taken with severe general abdominal pain and vomiting, October 2, 1892. Next day pain was present on deep pressure over McBurney's point. Occasional attacks of vomiting.

October 4th. Consultation with Dr. Noyes. Dulness on percussion in right iliac region; localized point of pain and circumscribed sense of resistance. General condition good. No pain on hyperextension of right thigh. Vomiting ceased. Temperature and pulse slightly elevated.

October 19th. Dr. Noyes in counsel. Symptoms and physical signs have not varied a great deal during last two weeks. Mass can still be detected in right iliac region.

October 22d. Same symptoms and signs with sweats. Dr. Noyes again in counsel. Operation agreed upon.

October 23d. I operated, being assisted by Dr. Noyes and Dr. McCusker. An incision three inches long was made, the centre of which was over the most prominent point of the mass in the right iliac region, parallel with the outer border of the rectus muscle. When the transversalis fascia was reached an aspirator needle was introduced twice, without entering the abscess cavity; a third time by causing the needle to enter obliquely and just to the left of the median line pus was found. An incision was made with the needle for a guide and five ounces (estimated) of fetid pus evacuated. Two silk sutures closed the angles of the wound. Coils of intestine could be felt in the cavity but not the appendix. The wound was irrigated with 1 to 2,000 sublimate solution and a double drainage-tube inserted and an antiseptic dressing applied.

December 1st. Patient made an uneventful recovery. Wound entirely healed, August, 1893.

CASE III. W. R. P., male, aged thirty-five, married.

I saw this case in consultation with Drs. P. H. Keefe and Wheeler, of Worcester, and McCusker, of Providence, on December 7, 1892. This patient gave a history of having had an attack of appendicitis one

year previously, by which he was confined to the room ten days. He has had slight pain in the right iliac region occasionally since then.

November 30th. During the night he was taken with slight general abdominal pain and vomiting. He had been working during the day and went to bed feeling as well as usual.

December 1st. Temperature 102°, pulse 120. General abdominal pain.

December 2d. Resting comfortably. Temperature 100°, pulse 110.

December 5th. Pain, dulness and rigidity of muscle in right iliac region. Pain most intense over McBurney's point. Temperature 99.4°, pulse 100.

December 6th. Conditions same as previous days. Bowels regular every day.

December 7th. Pain over McBurney's point, sense of resistance and dulness on percussion over an area four inches in diameter, just to the left of the right anterior superior spine of the ileum. No pain on moving right thigh. No chills or sweats and no fluctuation could be detected. Temperature 99°, pulse 84. Operation recommended. Assisted by Drs. Keefe, Wheeler and McCusker, I made an incision three inches long over the centre of the area of dulness and parallel with the median line. The skin, fat, external oblique, internal oblique and transversalis muscles, with the transversalis fascia were divided. An aspirator needle was then introduced and pus withdrawn. The peritoneum was now incised and three ounces of fetid pus evacuated. Appendix not found. The cavity was irrigated with 1 to 2,000 corrosive sublimate solution, a rubber drainage-tube introduced and an antiseptic dressing applied.

January 12, 1893. The wound was entirely healed.

August 26th. The patient works every day and has had no hernia or trouble since January last.

CASE IV. J. H. S., male, aged nineteen.

I saw this young man December 19, 1892, at the request of Dr. O'Keefe, his attending physician. The patient was in good health until ten days ago, when he was taken with pain in the "pit of the stomach" while at work. The pain continued and two days later was localized in the right iliac region. The third day a mass could be detected in the same region. The treatment consisted of warm poultices, anodynes and laxatives. On examination, pain was present on pressure over McBurney's point, an area of dulness about three inches in diameter with the above point as a centre and a feeling of resistance over the same area. Fluctuation could not be detected. Temperature and pulse slightly elevated. Operation advised.

December 20th. Patient etherized by Dr. O'Neil. Assisted by Dr. O'Keefe, I operated by making an incision three inches long, parallel with the outer border of the rectus muscle, and over the most prominent point of the mass. The skin, abdominal muscles and peritoneum were divided and five ounces of pus (estimated) removed from a cavity which presented. The intestines forming the inner wall of the abscess cavity could readily be felt, but a careful search failed to reveal the appendix. The cavity was irrigated with a 1 to 2,000 corrosive-sublimate solution. A rubber drainage-tube introduced, two silk sutures to close the angles of the wound and an iodoform and corrosive-sublimate gauze dressing applied. The wound was irrigated daily for a time and dressed as before mentioned. The patient made an uninterrupted recovery.

September 6, 1893. Patient has had no recurrence of the disease.

CASE V. A. F., female, age eighteen, domestic.

March 8, 1893. Patient was seized with severe pain, localized in the right iliac region. In a few hours she vomited a greenish fluid. A few hours afterwards she had a chill. She was confined to her bed until March 11th. She then rode in the steam and horse cars about six miles to her home, where she again went to bed suffering severe pain in the right iliac region.

March 14th. She was admitted to St. Joseph's Hospital. Examination shows greatest point of pain over McBurney's point; circumscribed area of dullness two inches in diameter. Sense of resistance on palpation over same area. Temperature 100.8°, pulse 112.

March 15th. Operation. Present, Drs. Collins, Noyes, Mitchell, Chesboro and O'Neil. Bichloride-of-mercury poultice over abdomen during the night. Field of operation rendered aseptic. Patient etherized. An incision about three inches long was made over tumor, parallel with the median line, down to the peritoneum. Fluctuation could be detected at the bottom of the wound, and the finger was passed through into an abscess cavity. About two ounces of fetid pus was removed, and the abscess cavity irrigated with boiled water. Appendix was not found. A counter-opening was made in the loin, and a rubber drainage-tube passed through the wounds. A glass drainage-tube was also passed into the primary wound. Irrigation again with boiled water, and two sutures of silkworm-gut at angles of primary incision. Iodoform and sterilized gauze, cotton and a bandage applied. Patient rallied well from operation. A warm-milk diet.

March 16th. Patient restless during night, and slight pain during the day.

March 17th. Dressing removed. Wound irrigated with corrosive-sublimate solution (1 to 2,000). Antiseptic dressing applied. Temperature, A. M., 99.9°; P. M., 99.6°. Pulse, A. M., 88; P. M., 96.

March 19th. Dressed. No pain.

March 22d. Dressed. Rubber drainage-tube removed. Glass tube allowed to remain. Temperature and pulse normal.

March 25th. Dressed. Slight amount of fluid feces escaped through wound.

March 31st. Dressed. Drainage-tube removed. Counter-opening entirely healed.

April 8d. Dressed. Enemas for constipation.

April 18th. Wound entirely healed.

May 4th. Patient allowed to sit up.

May 10th. Patient discharged cured.

CASE VI. H. F. R., male, East Providence, R. I. Age fifty, gardener.

This man I first saw at noon, June 27, 1893, in consultation with Dr. Mahoney. He had been at work the previous day, but had to leave his work in the afternoon on account of pain in the abdomen, most severe in the right iliac region. He had more or less abdominal pain for the last week. Temperature 100°, pulse 96. Sweats. Pain on pressure over McBurney's point. Dullness on percussion over an area three inches in diameter in right iliac region. Circumscribed sense of resistance. Could not feel a distinct tumor or fluctuation. Operation advised.

At 5 P. M., Dr. Mitchell concurred in the diagnosis, and advised operation. Assisted by Drs. Mahoney

and Mitchell, I made a four-inch incision, parallel with the median line, over the area of resistance and through the abdominal wall. When the peritoneum was reached, by the aid of an aspirator, some pus was withdrawn, and with the needle as a guide, the abscess cavity was opened. The cavity was only about one inch in diameter, and contained about two drachms of pus. The appendix was not found. Intestine formed the inner wall of the abscess. A rubber drainage-tube was introduced to the bottom of the wound, and two silkworm-gut sutures to partially close the incision. Irrigation with corrosive-sublimate solution (1 to 2,000) and an antiseptic dressing. Recovery uneventful.

August 28, 1893. Scar firm. No evidence of hernia. Patient walks about, and is in good condition.

(To be continued.)

Clinical Department.

A CASE OF CONCEALED ACCIDENTAL HÆMORRHAGE DURING THE FIRST STAGE OF LABOR, WITH RECOVERY OF MOTHER UNDER CONSERVATIVE TREATMENT.

BY EDWARD REYNOLDS, M.D.

On the 31st of last December I was asked by Dr. F. C. Murphy to see with him a primipara of thirty-eight, who had been subject to asthma and in poor health for some time, but had been in unusually good condition throughout her pregnancy. Labor began in the evening of December 29th; a few hours later Dr. Murphy was called, and found the cervix extremely long and rigid, the external os patulous, and the internal os about the size of a ten-cent piece; a little later in the evening the pulse rose suddenly to 160, and the patient felt faint, but as she gradually rallied somewhat, no treatment was adopted. During the night of the 29th and the day and night of the 30th moderate labor continued, and the pulse decreased gradually in rapidity. During the day-time of December 30th the patient became jaundiced, and began to look highly cachectic.

When I saw her at 10 A. M., December 31st, the pulse was 110, the skin was extremely sallow, the conjunctivæ slightly yellow. The patient was feeble and apathetic; the cachexia was marked, and her appearance resembled that of advanced malignant disease. The appearance of the abdomen was very peculiar. The uterus was rather small and extremely prominent, the epigastrium sinking rapidly away behind the fundus. On palpation, the fundus was tonically firm and rounded, suggesting the presence of unbroken membranes. The head presented. There was a tonic contraction of considerable intensity, accompanied by feeble exacerbations. On vaginal examination, the external os was soft and thin, about half dilated, and hanging away from the head; while the internal os, slightly larger, was hard and rigid, and pressed firmly against the head. The fœtus was moderately macerated, and a portion of its scalp, filled with fluid, occupied the cervical canal. Under ether, Dr. Murphy easily extracted a six-pound child by forceps. With the first attempt at expression the placenta was forcibly expelled, and was followed by about a quart of dark, old-looking clot.

The patient rallied well from the ether, and subsequently made a rapid convalescence.

Though forceps are not strictly applicable to much macerated heads, they were used here, on the ground of my belief that the extraction would be easy, and that the head was sufficiently firm to offer a secure grasp, a belief which was justified by the result. I think it probable that the blood was extravasated behind the placenta on the evening of the 29th, at the time of the sudden rise of pulse. The foetal heart had not been listened for at that time, and it is impossible, of course, to state that the death of the child was due to the hæmorrhage and the consequent detachment of the placenta; but as the mother had felt active movements shortly before that time, and as some previous experiences lead me to believe that maceration may become well advanced in a period of forty-eight hours in utero after the death of the child, I am inclined to believe that the hæmorrhage was the cause of the foetal death in this case. It is an interesting question whether the apparent jaundice could be hæmatopoietic and due to the hæmorrhage. The case is, at all events, well worthy of record from its extreme rarity.

INTESTINAL ANASTOMOSIS (WITH SENN'S PLATES) FOR CANCEROUS OBSTRUCTION.

BY J. W. ELLIOT, M.D.

THE patient was a feeble man, sixty years old. In August he had an attack of vomiting and diarrhoea. In September he began to lose his strength and to have attacks of dizziness. He also had a serious stoppage of the bowels, with pain on the right side, which was relieved by castor oil. He soon found that solid food gave him colic, he therefore took only liquids. In October he had more pain on the right side of the abdomen, and the movements became more difficult. Then the abdomen began to swell.

In November all his troubles became worse; he eat less, and had more pain. He then entered the Massachusetts General Hospital. There he vomited for four days, eat nothing, and was kept alive by nutritive enemata. He improved somewhat in his general condition, but had absolutely no movements of the bowels. No tumor could be felt.

Operation.—On December 15th the abdomen was opened, and the bowel was found to be completely obstructed by a cancerous mass in the cæcum. An anastomosis was then made, with Senn's plates, between the colon and the ileum. The operation did not take more than fifteen or twenty minutes; the patient, feeble as he was, had little or no shock. He made a rapid recovery. His bowels moved in twenty-four hours, and he took solid food on the fourth day.

It is now nearly three months since the operation. He has free and natural movements of the bowels, and has gained twenty-two pounds. He has no pain, and feels perfectly well. The growth has increased in size, and can be plainly felt in the abdomen. I should advise its removal if he were a stronger man.

I consider intestinal anastomosis one of the greatest advances in surgery; and it is difficult to understand why this very valuable operation has not yet been taken up in Boston, Dr. Homans's case being the only one on record. The operation is very quickly and easily done; and Dr. Senn deserves great credit for perfecting the technique. The advantages to the patient of an intestinal anastomosis over an artificial anus are enormous.

Medical Progress.

RECENT PROGRESS IN THORACIC DISEASE.

BY GEORGE G. SEARS, M.D.

TUBERCULOSIS AS A CAUSE OF PLEURITIC ADHESIONS.¹

SCHLEUBER gives the results obtained from 106 autopsies, but 21 of which showed no pleural adhesions. Among the remaining 85 the adhesions could be attributed in a number of cases to affections of the lungs other than tuberculosis, or to cardiac disease. Leaving these cases out of consideration, there remained 57, in 33, or 57.9 per cent, of which the adhesions, from the macroscopic examination, could be referred in all probability to a tuberculous cause. Schleuber is of the opinion that these figures would have been increased rather than diminished by the use of the microscope.

PECULIAR ODOR OF THE BREATH OF TUBERCULOUS PATIENTS.²

Rosenbach calls attention to a peculiarity of the breath of tuberculous patients, slightly resembling that of mild cases of putrid bronchitis, but differing from it in having a disagreeably sweet quality. It may become apparent in the neighborhood of the patient even in the absence of expectoration. It adheres to expectorated matter but feebly, being probably dependent on some volatile substances. It is only present in the exhaled air, and thus becomes most evident when the patient coughs or breathes with open mouth. It is a sign of unfavorable prognostic significance, even though the other manifestations in the case appear favorable. It is often present when the destructive process is not marked, and is most noticeable when the physical signs are unobtrusive. It is almost always an associated manifestation of disseminated broncho-pneumonic consolidation. It is wanting in cases of extensive infiltration, when cavities have formed and also when the sputum is copious. In a large number of cases in which this symptom was observed hæmoptysis occurred. Night-sweats, anorexia and febrile exacerbations were also frequently noted. The phenomenon is of diagnostic significance as it early indicates the occurrence of a morbid process in the lungs, and should therefore be sought for in all doubtful cases. To insure against a possible source of error the mouth and teeth of the patient should be first thoroughly cleansed.

THE DISINFECTION OF TUBERCULOUSLY-INFECTED HOUSES.³

Delepine and Ransome give the result of their efforts to disinfect rooms in which a phthisical patient has lived by chlorine, or more correctly suchlorine. Pieces of paper were carefully sterilized in glass capsules, and then infected with tuberculous material, either sputum or pure cultivations of the bacillus (human in most cases, avian in a few). The capsules were sealed, the sputum or cultivation being allowed to dry on the paper, and were not opened until just before the acid was poured on the chlorate of potash, and were again sealed when the room was reopened. Rabbits and guinea-pigs were then inoculated with small pieces of infected paper or superficial scrapings

² Wien. Med. Presse, 1893, No. 28; American Journal Medical Sciences, October, 1893.

³ British Medical Journal, November 4, 1893.

mixed with sterilized bouillon. In nine experiments made with three different kinds of sputum the results were unsatisfactory; in some cases complete disinfection seems to have been obtained, but the control experiments showed that some sputa were not as virulent as others. In six experiments made with pure cultures of the bacilli of human tuberculosis distinct evidences of the disease were observed within three or four weeks after inoculation. They therefore conclude that this method of disinfection, as well as that with sulphurous acid, which they have also investigated, is ineffectual. From some laboratory experiments with an old method of disinfection (not given) they hope before long to give practical means of effectually disinfecting places that have been contaminated with tuberculous products.

CONSUMPTION HOSPITALS AND TUBERCULOUS DUST.

The *British Medical Journal* (September 16, 1893) says that "the steady drift of opinion, especially among the younger of our physicians, in favor of the infectious nature of tuberculous phthisis has led us to make some inquiry at the hospitals especially devoted to the treatment of consumption as to the nature and extent of the precautions which they have thought well to take, or the warnings which they have thought it desirable to give to their patients, with the object of preventing or limiting the spread of the disease." The methods adopted by the various hospitals are severally reported, but are too long for reproduction here. They unite in stating that the chief way in which the infectious material enters is with the inspired air in the form of dust, and are strenuous in their efforts to keep the sputum wet until it is removed, some antiseptic, usually carbolic acid or occasionally a solution of caustic soda if the expectoration is very adhesive, being used in the cups. The stools are also quite generally disinfected. They are much less united in their treatment of the handkerchiefs, which by some authorities are prohibited altogether, while by others they are allowed, even though the danger caused by them is admitted. No precautions are generally taken regarding the soiled clothes; though in one case is taken that the dirty linen used by the officers, nurses, etc., is not sent to the same laundry as that of the patients, "an arrangement probably more satisfactory to the officers than to the general public." They are equally illogical in their dealings with the general dust of the institutions, which is removed by dry cloths and brooms, reliance being chiefly placed in an abundance of fresh air for rendering it innocuous. The journal mentions with approval the position taken by some of the provincial authorities, the Lancashire people, for example, not being content with the expression of a pious opinion on the subject, but print and distribute warnings, and in some places receive an informal notification of cases of tuberculosis, and even go to the expense of free disinfection of houses where consumptives dwell.

TUBERCULOSIS OF THE BRONCHIAL GLANDS AND ITS RELATION TO THE TUBERCULOSIS OF CHILDHOOD.⁴

Neumann sums up an interesting paper on this subject as follows:

Tuberculous infection in children is usually at first localized in the bronchial lymph glands. It is very common in the first years of life, and results from inhalation of the infectious material. This method of

infection may be prevented by proper hygienic regulations, which, though at times difficult to obtain in private practice, should be demanded in all public institutions. From the bronchial glands infection either rapidly spreads through well-known anatomical paths or it remains latent for an indefinite period, until its activity is finally excited by some condition (catarrh or inflammation of the respiratory tract) in which the glands are secondarily affected. At times, however, it may remain permanently latent or cure result from calcification. Diagnosis is only possible in advanced cases, and only then when the condition of the gland is not masked by affections of other organs. So long as they are simply tuberculous, but not enlarged or adherent to neighboring organs, they give rise to no signs or symptoms, while, on the other hand, the process which started from them may have produced such marked pathological changes in their neighborhood as to conceal the original trouble. Even when an autopsy has shown that diagnosis was possible, it has not always been made; nevertheless, cases comparatively frequently appear where a consideration of the possibility of an earlier infection (heredity, measles, etc.), combined with the rational and physical signs, makes their presence more or less probable. Especial weight is to be laid on the presence of a peculiar cough resembling pertussis in its paroxysmal character, and the presence of a very loud, indeterminate, though usually bronchial, respiratory murmur in the neighborhood of the upper thoracic vertebræ. The difficulty in diagnosis is well illustrated by a case reported by Stoll,⁵ occurring in a girl ten years old, in which the symptoms were so obscure that it was impossible to determine the seat of the disease until the autopsy, which showed a perforation of the trachea on a level with its bifurcation, through which a gland about the size of a walnut emptied itself. Beneath this large one were several others with softened centres. The trachea itself was obstructed by a plug of pus, situated above the perforation, which filled up the whole lumen and was probably the immediate cause of death.

CURE OF EMPYEMA.⁶

Aufrecht describes his progress through the various methods which have been devised for the treatment of empyema. After an experience with four cases he discarded aspiration as a means of cure, and practised incision and drainage, but has now reached the conclusion that resection of a rib is by far the most satisfactory proceeding, as it obviates the danger of hæmorrhage, allows free exit for masses of fibrin and prevents the too rapid closure of the opening, which by the simpler method could sometimes be kept open only by a silver tube. He selects a rib near the angle of the scapula, unless contraindicated by pleural adhesions or by the very weak condition of the patient. In the latter case he chooses the axillary line, as there is much less chance of death during the operation if the dorsal position be maintained. Beside the preliminary puncture to ascertain the presence of pus, he is accustomed to make a second after resection through the free pleura. He recommends at first daily irrigation. Cure results from the fact that with each inspiration the lung collapsed by the operation must dilate if the size of the opening in the chest-wall is smaller than that of the primary bronchus leading to the part. In addition,

⁴ Dent. Med. Week., 1893, Nos. 9-17.

⁵ Centralblatt f. klin. Med., 1894, No. 3.

⁶ Dent. Arch. f. klin. Med., Bd. III, Heft 1 and 2.

however, it is necessary that the pleura itself should be in a condition to allow adhesions to form between its two surfaces. The slow subsidence of the pleural inflammation in some cases to the point where this is possible, explains their occasional protracted convalescence.

LEUCOCYTOSIS IN GROUPOUS PNEUMONIA.⁷

Laehr reports sixteen very carefully studied cases of pneumonia in reference to the relationship of the leucocytosis present in them to the temperature, amount of infiltration and the severity of the infection, as well as in its significance in diagnosis, prognosis and treatment. The cases showed a marked correspondence between the height of the fever and that of the leucocytosis, in that they rose and fell together, but the correspondence did not go so far as to show that the greatest number of leucocytes was always associated with the highest temperatures. A certain parallelism was also observed between the former and the amount of infiltration, but that other factors were present is shown by two cases, both powerfully built men, in one of whom the whole right lung was affected and yet the leucocytes numbered only 10,000 to 14,000, while in the other, though but one lower lobe was attacked, 51,000 were counted. This dissimilarity Laehr accounts for by the individual peculiarity of the patient and the force of the infection. Regarding diagnosis, a blood-count may prove of great value in distinguishing early cases of pneumonia from typhoid, meningitis, influenza and probably miliary tuberculosis, in which little or no increase of the white elements has been found. In prognosis it may with probable safety be said that if the number of leucocytes does not diminish with the fall of temperature that the process has not come to an end, or if it sinks with the temperature to normal, but rises by several thousand later, a recrudescence of fever, or the appearance of some complication, may be confidently looked for. In the most severe cases his experience is in accord with that of Haller, Rieder and von Jaksch, in that either no leucocytosis was observed or else a very slight increase.

Whether these observations will prove of value in indicating a method of treatment, such as the administration of drugs like jaborandi, antipyrin, antifebrin or nuclein, which are said to increase the number of white corpuscles, as recommended by von Jaksch, is yet to be proved, as it is not yet known how far an inflammatory leucocytosis is protective against disease germs, much less than an artificially produced one. The usefulness of cold baths in pneumonia receives support in this respect from Winternitz, who claims that they too increase their number.

INCISION AND DRAINAGE IN PYOPERICARDIUM.⁸

Sievers gives the histories of the eleven cases of purulent pericarditis treated by incision and drainage, which have been previously reported, and adds one of his own occurring in a woman twenty-two years old, who died thirteen days after operation.

He draws the following conclusions:

- (1) That the operation is a proper one, that it produces no disturbance of the heart's action and offers the only chance of cure.
- (2) That in many cases it may lead to full recovery (five cases out of twelve), and that in complicated

pyæmic conditions it may at least better the condition of the patient or prolong his life.

- (3) That the incision is best made in the fourth or fifth interspace, a few centimetres to left of sternum, and drainage introduced, but irrigation should be omitted.

CYSTIC DEGENERATION OF THE MUSCULAR FIBRES OF THE HEART.⁹

Meigs describes a form of myocardial degeneration in which "the destructive process, in its most extreme form of development, removes the whole of the muscular substance from the centre of the fibre, no part of which, when examined by the microscope, will present the usual appearance of muscular tissue except the thin outer walls, and even these may show only in places the cross-markings characteristic of heart muscle." The muscle nuclei often lie loosely in the cavities without attachment to the remaining tissue. The hollowing-out, when most extreme, is apt to be near the ends of the fibres toward their point of origin or insertion, but will be unmistakable in all parts of the heart. "The fact that the muscular fibres of the heart are penetrated by capillaries and are not, therefore, truly solid bodies, together with the appearance of these spaces, leads to the almost inevitable conclusion that the process is one of cystic degeneration," a capillary becoming blocked in two places, the portion between them dilating and thus forming a cyst. The assumption that they are minute aneurisms is negated by the nature of the material lying within the cavities, which is amorphous and granular or consisting of yellowish pigment in irregularly-shaped flakes. It is impossible at present to predict from clinical manifestations which cases will present this curious change, as it was absent in cases of brain syphilis, sarcoma, general miliary tuberculosis, Bright's disease, pulmonary phthisis, typhoid fever, pneumonia, dysentery, epithelioma of the bowel and aneurism, and present in what was clinically recognized as organic heart disease, Bright's disease, typhoid fever, ulcerative endocarditis and in young infants that died of wasting.

BRADYCARDIA DURING CONVALESCENCE.¹⁰

In speaking of the slow pulse (60 or less) which is sometimes met during convalescence from acute diseases Dehio says that we have little positive knowledge of the cause of its appearance or the anatomical changes which accompany it. With the establishment of convalescence the pulse falls with the temperature, but the fall continues below the normal rate until its beats number only sixty a minute or even decidedly less. This condition in mild cases lasts but a few days to a week, and, with this exception, the patient presents no noteworthy symptoms. The heart seems normal though the apex beat is weak, the pulse is easily compressed and often dicrotic, at times, also, slightly irregular. In the severe forms, however, the patient shows signs of great prostration, the lateral area of the heart's dulness is increased, its action is irregular and intermittent, and a systolic murmur is heard over the left ventricle. In order to determine whether this resulted from some change in the heart itself or was of central origin, Dehio injected hypodermically one-sixtieth to one-thirtieth of a grain of atropine, which has the power of paralyzing the cardiac

⁷ *Bal. klin. Woch.*, 1898, Nos. 36 and 37.

⁸ *Zeitschr. klin. Med.*, 1898, Bd. xxiii, p. 26.

⁹ *Transactions College of Physicians, Philadelphia*, 3 s., vol. xiv.

¹⁰ *Deut. Arch. f. klin. Med.*, Bd. lli, Heft 1 and 2.

terminations of the vagus nerve. In a mild case he found that the number of beats was increased to the same degree as under normal circumstances, while in the more severe forms this increase was much less marked. He, therefore, concludes that the cause is to be found in the heart itself and not in some change in the nervous mechanism, such as an increased irritability of the vagus or an atonic condition of the medullary centre of the accelerator sympathetic fibres, and is, therefore, an evidence of cardiac weakness, and of the same import as other symptoms (intercurrent attacks of rapid pulse, irregularity, palpitation) of this condition, many of which were present in his cases. The occurrence of this symptom is comparatively rare as he only met with eight cases in his hospital clinic during the past semester. He suggests the probability of its being due to the toxic action of some specific material produced in the organism during the course of an infectious disease which causes no anatomical change in the heart, but considers it probable that an individual predisposition also exists, otherwise it would be difficult to explain why it was not present in all convalescent patients and why it was not more common after severe infectious cases than after mild ones.

THE SCHOTT METHOD OF TREATING CHRONIC HEART DISEASE.¹¹

Babcock, who has had a personal experience as a patient, gives a brief account of the so-called Schott Method. In theory, it is the same as that of Oertel, the production of cardiac hypertrophy through increase of its physiological function, but can be much more generally applied, as it is contraindicated only in aneurism of the heart or large vessels, or in advanced arterio-sclerosis. Nevertheless, as the powerful stimulation produced by the baths is capable of doing great harm, care and experience are necessary in its employment.

The method consists in the administration of warm baths, either simple saline, or containing a large percentage of carbonic-acid gas, the amount of the saline constituents and the carbonic acid being gradually increased as the patient becomes accustomed to them. The temperature varies between 92° and 86° F., and the duration from five to twenty-five minutes, being short at first, and gradually lengthened. The baths are occasionally omitted for a day. The patient is under general hygienic and dietetic restraints, and, in connection with the baths, gymnastic exercises, consisting of resisted movements of the extremities and body, are given by, preferably, a trained assistant. A single movement should not be immediately repeated, and each one should be followed by a short period of repose, and should not be made in such a way as to cause acceleration of the pulse or respirations.

As a result of the baths there is a slowing of the pulse and an increase in volume and strength, while its irregularity lessens, or even disappears. The increased vigor of the cardiac contraction permits a positive diminution in the size of a dilated heart, which can be demonstrated by accurate percussion practised before and after a bath. Among other effects is a sense of well-being, particularly of ease and lightness in the chest, relief of dyspnoea and increased diuresis. The effect of the gymnastics is similar to that of the baths on the pulse and heart, but the favorable effects are less lasting.

¹¹ Journal American Medical Association, November 11, 1893.

Functional as well as organic disorders, are strikingly benefited, Schott claiming highly satisfactory results in cases of exophthalmic goitre. Although Schott's results are obtained by the natural waters of Bad Nauheim, there seems no reason why artificially-prepared waters should not prove efficacious.

FUNCTIONAL INSUFFICIENCY OF THE VALVES OF THE LEFT HEART.¹²

Dombrowski, in commenting on the usual explanation given for inorganic insufficiency of the mitral valve, that it results from distention of the orifice, the flaps being unable to completely close it, says that such dilatation is by no means invariably found, and, besides, the orifice is surrounded by a tendinous ring whose resistance is not easy to overcome, as he has proved by several experiments. He removed the heart from the cadaver, ligatured the aorta, and then, through an opening made at the apex, forced in water under strong pressure, in spite of which the valve allowed no leakage. Only when the cardiac dilatation became very considerable did the valve prove insufficient, and even then the orifice preserved its normal dimensions. Moreover, Wulf has shown that the surface of the flaps greatly exceeds the size of the orifice, while Kirschner and Garcin claim that the aortic half alone suffices to cover it, even when considerably dilated. Clinical experience is also opposed to the view usually held; for the transitory character of the insufficiency—as shown by the behavior of the murmur, which disappears, and then, perhaps, reappears after a certain time—does not accord with a distention of the orifice. The cause of the insufficiency must, therefore, be sought in the muscular dilatation producing a separation of the insertions of the papillary muscles, which in systole cannot approach each other near enough to allow the valves to close, the contraction of the papillary muscles only increasing the difficulty. He would, therefore, prefer the term "functional" to that of "relative insufficiency."

The aortic valve is no exception to the general rule that all the valves of the heart may become insufficient, but it seems to be a rare event, as he has been able to find but a few cases reported in literature. He adds two others proved by autopsy from his own experience.

In contrast to the functional insufficiency of the mitral valves, that of the aortic is always relative, and depends on a dilatation of the aorta, resulting from increased blood-pressure followed by atheromatous changes in the artery. It is a terminal symptom, the precursor of death, and its recognition clinically is, consequently, of considerable importance. It is not always possible to distinguish it from a true aortic lesion but in the differential diagnosis stress should be laid on the age of the patient (it never occurs under fifty), the signs of general atheromatous changes, its slow and insidious development with probably a long history of symptoms of increased blood-pressure, oppression, palpitation and vertigo, to which should be added the signs characteristic of dilatation of the aorta, pulsation in the neck, dullness under the manubrium, and the metallic quality of the second cardiac sound.

A STRONG MAN, on exhibition in London, lifts two horses with their riders at the same time, the total weight being about four thousand pounds.

¹² Rev. de Méd., September 10, 1893.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

THIRTY THIRD ANNUAL MEETING, January 13, 1894, the President, DR. CHARLES M. GREEN, in the chair.

DR. W. L. BURRAGE read by invitation a paper on
THREE YEARS' EXPERIENCE WITH ELECTRICAL
TREATMENT OF FIBROID TUMORS OF THE UTERUS,
WITH A REPORT OF FORTY-FOUR CASES,

of which the following is an abstract:

In the three years from October 18, 1890, to October 18, 1893, he had seen, in hospital and private practice, 98 cases of fibroids; 44 of these had been treated with electricity after the method of Apostoli, and had received at least six treatments each. Apostoli had been followed rigidly, and the cases had been kept under personal observation for as long a time as possible, in order to arrive at accurate conclusions as to permanent results. The records of the 44 cases were presented to the Society in tabular form. All cases of doubtful diagnosis had been excluded from the tables, and a majority of the whole number had been subjected to an ether examination. For details of treatment the members were referred to a previous paper on technique by Dr. Burrage, published in the *Boston Medical and Surgical Journal* for November 26, 1891. Most careful measurements of abdominal girth and uterine depth were taken with the same steel tape in every case.

It is impossible to take absolute measurements of the size of fibroids, owing to the varying condition of emptiness or fulness of the intestines, bladder and rectum, the changing thickness of the fat of the parietal walls and omentum, and the changing shape of the tumor. Fibroids vary in size even from day to day, owing to temporary engorgement or depletion. It is a well-known fact that they are smaller just after the catamenia and larger before and during. The relative size must be determined by tactile sense and by repeated examinations (an anæsthetic is an advantage) under as nearly similar conditions as possible.

Tonics and other forms of treatment were studiously avoided, so that the results might be fairly attributed to electricity.

Thirty-five of the cases are analyzed with reference to anatomical results. Each had at least six treatments with galvanism, either intra-uterine or by puncture, and with intensities rising fifty milliamperes, and, in addition, had been under observation for at least four months from the beginning of electrical treatment, a majority from one and one-half to two years. The entire 44 cases are later analyzed as to symptomatic results.

First, as to anatomical results, the effect of electricity on the size of fibroids:

Of 35 cases, 9 (25.7 per cent.) showed a decrease in size at the end of periods varying from one to eight months from the beginning of treatment; but in six of these nine, at the end of periods of time varying from one to two and one-half years, the tumor was as large as at the beginning or larger. The other three were lost sight of, one in four and the other two in eight months. The tables furnished no positive evidence that any of the tumors were permanently lessened

in size as a result of electrical treatment. Seven cases out of 35 (20 per cent.) were somewhat larger at the end of one and one-half to two and one-half years. Deducting from 35 these 7 cases, and the 3 in which the tumor was smaller when the patient was lost sight of, and we have 25 as the number of cases in which the tumor remained of the same size, or 71 per cent. The writer had failed to observe rapid disappearance of fibroids, but had noticed marked decrease in the size of separate nodules following puncture. Electricity clears up pelvic inflammation; a fibroid previously fixed becomes movable; a mass made up of exudate and ovary and tube disappears under treatment. The fat in the abdominal wall is increased in thickness. Measurements of uterine depth are not materially affected. Intra-uterine applications of galvanism have a temporary curative effect on the endometritis of fibroids, but not a permanent effect, the endometritis returning after several months, just as it does in most cases after curetting.

A case illustrative of the above was that of a patient treated with intra-uterine galvanism for three months, eleven treatments, 40°-70°. On doing a hysterectomy, a year later, the uterine cavity was found lined with soft, velvety tissue easily scraped off a glistening white base.

Cervical stenosis following high intensities occurred in a certain proportion of the cases. It is to be guarded against by beginning treatment with the tip of the electrode, as near the fundus uteri as possible. Stenosis prevents subsequent treatment with larger electrodes. It has not caused dysmenorrhœa.

Second, the symptomatic results. The thirty-five cases are classified under four heads:

I. Those that were relieved of pain permanently.

II. Those that were relieved of flowing permanently.

III. Those in whom there was permanent improvement of general strength and ability to work.

IV. Those that experienced no permanent benefit.

Of I, there were 11 cases out of 19, in which pain was a prominent symptom, or 60 per cent.; of II, there were 7 cases out of 23 cases, in which flowing was a prominent symptom, or 30 per cent.; of III, there were 21 cases out of 25, where relief was possible, or 84 per cent.; of IV, there were 8 cases, or 23 per cent. Adding together I, II and III, and subtracting 12 for the cases inserted more than once, and the result is 27, the number of cases that received permanent symptomatic benefit, or 77 per cent. An analysis of the entire 44 cases with reference to temporary symptomatic relief gives 84 per cent. as benefited by electrical treatment. The figures make a very satisfactory showing when it is taken into account that the cases were treated for the most part in an outpatient clinic; that many of them, preferably treated at their houses, were obliged to travel long distances and wait their turn for treatment, and then go home often after a tedious ride in the cars and in inclement weather.

As to particular symptoms, electricity had no effect on a watery leucorrhœa in two cases. In two patients, it cured the uterine cough spoken of by French writers.

Summing up, we may say, that, on the whole, the anatomical results were unsatisfactory. Assuming that fibroids, if untreated, have a tendency to increase in size, we are justified in the conclusion that galvanism has an inhibitory effect on a majority of these tumors; 71 per cent. of the tabulated cases remained

stationary. Until we know more of the conditions that favor increase or diminution in their size, the laws of their pathological growth, we cannot say more. The symptomatic results, on the other hand, present a highly satisfactory showing, 77 per cent. being permanently cured. The low percentage of cures of hæmorrhage is to be attributed to the distorted shape of many of the tumors, making thorough intra-uterine treatment impossible, and to the fact that endometritis, the source of the hæmorrhage, will return if the cause is still present, whether the treatment has been by caustics, carbolic acid, etc., by curettement, or by positive intra-uterine galvanism. Intra-uterine galvanism for hæmorrhage has the advantage over curettement and the application of caustics, that it does not necessitate the administration of an anæsthetic with its attendant discomforts and risks, and is followed by no reaction. It is preferable to ergot and hydrastis, as it has a tonic instead of a depressing influence on the digestion, and its effect is more durable. Galvanism often succeeds where ergot and hydrastis have failed.

As regards the alleged danger of electrical treatment, it must be concluded that, if properly applied, it is without danger. It is contraindicated in pregnancy and acute inflammation, and that is all. An illustrative case of acute salpingitis confirmed by oosiotomy is cited. That galvanism causes abscesses and adhesions the writer believes to be false. Cases of pus-tubes treated for months with galvanism, with no change in symptoms and verified by subsequent abdominal section, are referred to; also cases treated with galvanism, intra-uterine, vaginal and by abdominal puncture, in whom, on opening the abdomen, no adhesions were found. Sensitiveness to galvanism has not been an indication of the presence of pus, although considered so by Apostoli.

As to puncture, the writer advocates vaginal puncture, but thinks this in many instances contraindicated, because of the likelihood of wounding the ureters, bladder and rectum. Intra-uterine treatment is to be preferred. All treatment should be begun gradually and with vaginal application, because intra-uterine and puncture treatments are more or less painful, and our women are not as phlegmatic and insensitive as the women who attend the foreign clinics. Faradism from the coil of fine wire is of great service in relieving the pain caused by high intensities of galvanism.

The results obtained in the cases included in the third classification — those permanently improved in general health and rendered better able to work — are extremely satisfactory, and alone justify the time and labor necessary for the proper application of electricity. The results are out of all proportion to those obtained from general electrization, and besides, it is more rational to apply the electricity as near the seat of disease as possible. The writer believes that fibroid tumors are not the harmless tumors they have been thought to be; although they seldom kill quickly, they wear out slowly, and many a woman leads a life of misery and suffering because the profession has believed and advised that nothing but hysterectomy could relieve.

As we learn more and more about these tumors, and appreciate better the symptoms to which they give rise, their laws of growth, the danger to the economy from long-continued pressure, and, as the technique of hysterectomy is improved, the speed in operating increased, and the mortality lowered, it is the writer's opinion

that total removal will be practised oftener and oftener and earlier and earlier in the life-history of fibroids. When such a radical measure is inexpedient, and it always will be in a certain proportion of cases, our duty is plain, we must relieve suffering. Electricity, on account of its safety, on account of its proved ability to relieve hæmorrhage and pain, and on account of its surety to improve the general health and strength, is the best means at our command with which to treat this distressing condition.

Conclusions. — (1) Hysterectomy is contraindicated in a majority of cases of fibroids, because of the high rate of mortality, and because it unsexes the patient, an important consideration in younger women.

(2) Electricity is the best therapeutic means at our disposal to combat pain, hæmorrhage, and impaired health and strength.

(3) Intra-uterine galvanism is most useful.

(4) We must not look for a permanent reduction in the size of the tumor.

(5) Galvanism, vaginal, intra-uterine, or by puncture, does not cause abscesses or adhesions.

(6) Galvanism is of no use as a means of diagnosing the presence of pus.

(7) Treatment by electricity, after the Apostoli method, is absolutely safe.

(8) Every case of fibroid tumor of the uterus should be under competent medical observation, because of the danger of malignant degeneration, kidney disease from pressure, complications during pregnancy, and the liability of the occurrence of pain and hæmorrhage and functional nervous disorders, especially during a delayed and protracted menopause.

DR. G. H. WASHBURN said he had watched a number of the cases reported by Dr. Burrage, and had himself treated a number of other cases. He recalled one case where a rapidly growing fibroid diminished rapidly after the second treatment by electricity. The first application had no effect except to make the patient more comfortable. After the second application there was a diminution in size, of one-third or one-half. This was the only case where he saw such marked diminution. In another case there was some diminution in size after six months' treatment. The results in other respects were most satisfactory. He would agree most thoroughly with Dr. Burrage's conclusions, that as our ability to operate on these cases increases so would the number of operations; and the careful statistics of Dr. Burrage shows us the scope of electricity, and that it is of great value within certain limits.

DR. M. H. RICHARDSON said that he had had no personal experience in the electrical treatment of fibroid tumors, for this was a branch of medicine in which he preferred to send his cases to the medical electrician. Patients had frequently come to him in whom the symptoms were so severe that the tumor could be removed only with the greatest danger. In such cases the patient's strength is so reduced by hæmorrhage and long suffering that the formidable manipulations of a hysterectomy are almost surely fatal. To leave the tumor untouched, however, means gradually increasing weakness, suffering and death. When the brilliant results of the electrical treatment of fibroids were first published, a safe middle course seemed at hand, by which the strength of the patient might be increased enough to enable her to undergo with comparative safety the radical operation, — even if we made allowances for the usual exaggerations of the merits of new

method of treatment. While the brilliant results from this method of treatment which were at first published have not been fully realized, yet the use of electricity in many advanced cases has so diminished both the pain and the hæmorrhage that the patients have been enabled to undergo successfully total extirpation. From the standpoint of the operating surgeon a hysterectomy for fibroids carries a considerable mortality. Deaths are due, first, to the weakened condition of the patient; and, secondly, to peritonitis from unavoidable contamination during the operation. With the patient in good condition, the results of the operation at the present time are very satisfactory indeed. Dr. Richardson's mortality is constantly decreasing, and yet he does not expect ever to be able to avoid fatal results in this class of cases.

Puncture of the tumor for the application of electricity the speaker regards as dangerous, because he has seen at times excessive hæmorrhage from small perforations of the enormous veins which sometimes ramify in the capsule of the tumor. He is now more inclined to advocate the early removal of these tumors than he was formerly, chiefly because of the vast increase in the dangers which attend advanced cases. On the other hand, he believes that one may easily go to the other extreme and become dangerously meddling in his efforts. Total extirpation of the uterus for a fibroid of small dimensions which is causing no trouble is unjustifiable except in the rarest instances. Even if the tumor is of considerable size, so long as it produces no symptoms except those of weight—so long as there is no excessive hæmorrhage, no pain or discomfort, and no evidence of pressure upon the ureters—the operation is unjustifiable, even with the present excellence of technique. Yet there is one consideration which must be borne in mind in advising against operation in these cases, and that is the possibility of malignant degeneration. This danger is always present, and is the only good reason for interference in the class of cases which is referred to. Dr. Richardson has rarely seen a malignant tumor of the uterus which has resulted from the degeneration of a fibroid. Certainly there have not been as many cases of hopeless malignancy as there have been of unnecessary death—if among unnecessary deaths are included those cases of fibroid which died after an operation that was not imperative. In his experience there have been two deaths after the removal of fibroids in which the symptoms were not distressing. In both, the operation was undertaken at the urgent solicitation of the patient for the relief of pain and disability; in both, life—endurable though not enjoyable—might have been prolonged for many years by palliative treatment.

As far as the speaker's observations have gone in his own practice and in that of his colleagues, the removal of a fibroid tumor of the uterus by hysterectomy is one of the most formidable of procedures. Even with the greatest skill and experience in operating, the mortality is considerable. He would welcome, therefore, any method by which either the operation might be rendered unnecessary, or the patient could be so improved as to enable her to undergo more safely the inherent risks of the radical operation.

Dr. E. J. FOSTER spoke of a case he had seen in consultation, where there were two fibroid tumors of the uterus, one subperitoneal and one submucoid. These were treated by electric puncture. The sub-

peritoneal tumor disappeared, the other tumor sloughed. The patient has since become pregnant.

Dr. EDWARD REYNOLDS said that his experience with electricity in other gynecological affections accords with Dr. Burrage, that it is of great value and as safe as any method of treatment. Its use tends to a surprising degree to relieve reflex nerve troubles.

Dr. J. W. ELLIOT believes in very early operation on fibroids in those cases of rapid growth, with frequent hæmorrhage, and debarring the patient from earning a living. Early operations give a very low mortality from fibroids. As the passing of a uterine sound may in careless or unskilled hands cause septiciæmia, so may and has the application of the electrode. In specialist's hands, as with Dr. Burrage, this can be done safely.

Dr. G. HAVEN would agree with Dr. Burrage that an exudate was absorbed by means of the electricity.

Dr. F. H. DAVENPORT said that the use of electricity in these cases needs, of course, special apparatus and much time; and it is a question whether this method should supersede the other methods we are in the habit of using. He had for two or three years been treating fibroids with electricity, and although he has had good results, he is not sure but that as good results might be obtained by other methods. Two series of cases treated in the two ways would be of great interest.

Dr. BURRAGE: I should like to ask Dr. Elliot if the case of peritonitis he has referred to was following puncture through the vagina or through the abdominal walls? As I said in my paper, I consider that the latter procedure involves too much danger to recommend it.
